The complete grapevine sequence will provide a resource that will open new avenues of research to answer many fundamental questions, and also will provide a new tool to stimulate the breeding of this economically important species. Indeed *V. vinifera* wine grape cultivars of commercial value were obtained by controlled crosses during the 19th and 20th centuries. In France, the variety Alicante Bouschet was bred by Louis and Henri Bouschet from 1829 to 1855 and was obtained from a tripartite cross between Aramon, Teinturier du Cher, and Grenache noir (Snyder, 1937). In Germany, the variety Muller-Thurgau was obtained in 1892 from a cross between Riesling and Madeleine royale (Dettweiler *et al.*, 2000). In South Africa, the variety Pinotage was obtained in 1925 from a cross between Pinot noir and Cinsaut (Orffer, 1979). However, plantings of wine grape cultivars recently developed from traditional breeding programs still remain limited, despite considerable work carried out during the second half of the 20th century (Alleweldt and Possingham, 1988). New cultivars are always assigned new names, contributing generally to their slow acceptance in the market place. The current interest in France about the cultivar Marselan, obtained recently from a cross between Cabernet Sauvignon and Grenache noir (Bouquet and Boursiquot, 1999), was likely stimulated by the disclosure that the two worldwide leading varieties (Cabernet Sauvignon and Chardonnay) were in fact obtained several centuries ago from crosses between older varieties (Bowers and Meredith, 1997; Bowers *et al.*, 1999).

Table grapes are not subject to the same constraints as wine grapes with regard to tradition and consumer acceptance, and conventional

breeding programs have produced numerous outstanding new cultivars during the 20th century, most of them seedless (Ledbetter and Ramming, 1989). Over the last 20 years, the efficiency of breeding for seedless berries was considerably improved with the use of *in vitro* embryo rescue (Cain *et al.*, 1983; Spiegel-Roy *et al.*, 1985). Molecular markers and genetic maps have been developed for the detection of quantitative trait loci (QTL) involved in seedlessness (Striem *et al.*, 1996; Lahogue *et al.*, 1998; This *et al.*, 2000; Adam-Blondon *et al.*, 2001; Doligez *et al.*, 2002; Mejia and Hinrichsen, 2003) and other berry characteristics, such as muscat flavor (Doligez *et al.*, 2006b).

But it is with rootstocks that breeding has had the greatest impact on viticulture. Until the end of 19th century, grapevine was propagated by layering or by hardwood cuttings. Since the introduction of the root louse Phylloxera in Europe during 1868, *V. vinifera* varieties are grafted on resistant rootstocks derived from several North American wild species, mainly *Vitis riparia*, *Vitis rupestris*, and *Vitis berlandieri*. This is probably the first and most significant example of a successful genetic solution against a major pest of cultivated perennial plants and the breeding of Phylloxera-resistant rootstocks adapted to different edaphic and climatic conditions, such as limy soils or drought, is the foundation of modern viticulture (Pouget, 1990). Most of these rootstock cultivars were selected at the end of 19th century, but breeding work is continuing in France, Germany, California, Brazil, and Australia. Resistance to lime chlorosis is still a major problem in some French vineyards (Pouget, 1980) and in Germany rootstock breeding is based on the use of complete Phylloxera resistance from *Vitis cinerea* (Schmid *et al.*, 2003). One of the current objectives is to improve resistance against the root-knot nematode *Meloidogyne incognita* (Cousins and Walker, 2002) and the soil-inhabiting nematode *Xiphinema index* that is the carrier of the grape fanleaf virus (Walker *et al.*, 1994; Bouquet *et al.*, 2000a). Molecular breeding holds great promise for the genetic improvement of rootstocks. Linkage maps have been constructed from a cross between two half-sib genotypes *V. rupestris* × *V. arizonica* that carry resistance to Pierce's Disease (PD) and *X. index* (Douceff *et al.*, 2004; Riaz *et al.*, 2006). Lowe and Walker (2006) have also developed a genetic map

from progeny of a cross between *V. champini* and *V. riparia* that may be useful for studying the genetics of many traits including nematode resistance and salt tolerance. In France, INRA scientists from Bordeaux, used progeny from a cross between *V. vinifera* cv. Cabernet-sauvignon and *V. riparia* and constructed a map for identifying QTLs involved in lime chlorosis tolerance and scion vigor (S. Decroocq and N. Ollat, personal communication).

If the use of interspecific hybridization in rootstock breeding was a considerable success, it is still controversial in wine grape breeding. In the genus *Vitis*, species other than *V. vinifera* produce berries with unfamiliar flavors. These flavors are evident in the wines of numerous interspecific hybrids, for example the “foxy” wines of the *Vitis* × *labruscana* cultivars of the New York State vineyards. Hundreds of hybrids with complex pedigrees involving *V. vinifera*, *V. rupestris*, *V. lincecumii*, *V. labrusca*, *V. riparia* and several other North American species were produced in France during the first half of the 20th century, firstly as phylloxera-resistant cultivars (“Direct Producer Hybrids”), then as downy and powdery mildew-resistant cultivars. Their wines were unfamiliar and were not widely accepted, although these hybrids were cultivated on more than 400 000 ha, due to their high productivity and hardiness. Several of these hybrids were prohibited in France as far back as 1934 and the majority of the others in 1955. This led to a drastic change of strategy in France resulting in the use of *Muscadinia* since 1975 (Bouquet, 1980, 1986; Merdinoglu *et al.*, 2003) in breeding efforts. Nevertheless, it should not draw attention away from the accomplishments in other countries, particularly in Germany, to breed resistant cultivars using some of these “French hybrids” (Chambourcin, Villard blanc, Seyval). The success of a cultivar such as Regent (Eibach and Töpfer, 2003) shows that there is still potential in the use of *Euvitis* germplasm for genetic improvement in the framework of an environmental-friendly sustainable viticulture. Molecular breeding, such as genetic mapping and marker-assisted selection, is currently being developed for disease resistance (Dalbo *et al.*, 2001; Pauquet *et al.*, 2001; Donald *et al.*, 2002; Fischer *et al.*, 2004; Akkurt *et al.*, 2006; Wiedemann-Merdinoglu *et al.*, 2006) especially with an aim to pyramid genes from *Muscadinia*

and *Euvitis* (Kozma and Dula, 2003; Eibach *et al.*, 2006; Moreira *et al.*, 2006).

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

The evolution of the range of grapevine varieties can be characterized by two words: shifting and simplification (Doazan, 2000). Throughout history, and particularly during the 18th and 19th centuries for which detailed and reliable documents are available, changing (shifting) varieties has always been a means of adapting to changes of viticulture practices imposed either by nature or by man. During the 20th century, however, we have observed a slowing down, if not a freezing, of this evolution concomitant with the emergence of the “Appellation d’Origine” notion, particularly in France. In addition, there has also been a simplification of the varietal range due to the development of an international wine trade based on a few traditional cultivars. This simplification has resulted in widespread ignorance about the genetic diversity that ensured the success of viticulture in the past and its long-term effects in the future have not been carefully considered. It seems to be a paradox that newly bred wine cultivars are not rapidly adopted by industry although their agronomic and enological potential have been intensively investigated using sophisticated methods not available during the adoption of traditional cultivars. The present generation within the wine industry may be too presumptuous to believe that success of traditional cultivars, based on today’s context, will continue forever on such unchanged basis. In fact, there is a general industry perception in some countries that to be successful a new wine cultivar must be very similar to, or if possible indistinguishable from the traditional cultivar that it is designed to replace except for the addition of a desirable trait such as disease or pest resistance. Thus, biotechnology offers a means of inserting new characters into the genome of traditional cultivars without changing any of their other characteristics, particularly wine typicity and quality (Bisson *et al.*, 2002). The best example of the rationale of transgenic breeding versus conventional breeding is the introduction in new wine cultivars of the genes *Run1* and *Rpv1* that

confer resistance to powdery mildew and downy mildew (Bouquet *et al.*, 2000b). Despite their great potential, the future of these “*Muscadinia*-derived” varieties is not ensured, and the positional cloning and sequencing of the gene *Run1* is currently under way, for direct insertion into the genomes of traditional premium wine cultivars (Barker *et al.*, 2005, 2006).

Rootstock cultivars currently used in viticulture worldwide were obtained from conventional breeding and this traditional approach is still practiced in several countries. The advantage with the transgenic approach for grapevine improvement lies in the potential to improve rootstocks particularly adapted to some types of soil and/or climate. The best example is the genetic transformation of the 41 B rootstock, perfectly adapted to the lime soils of the Champagne vineyards, for resistance to grape fanleaf virus (Mauro *et al.*, 2000). Furthermore, grapevine cultivars often have some characteristics or deficiencies that need improvement or correction but where the natural genetic variability in the *Vitis* germplasm is lacking or unusable in conventional breeding. The best example is the susceptibility of much, if not all *V. vinifera* cultivars to wood diseases such as Eutypa dieback, Esca (black measles), or black dead arm. In the case of Eutypa dieback a potential source of resistance may exist in *Vigna radiata* (Guillen *et al.*, 1998).

Despite the focus on the production of improved plants for commercial release (Colova-Tsolova *et al.*, 2001; Kikkert *et al.*, 2001; Bouquet *et al.*, 2003) it should not be forgotten that the ability to produce transgenic grapevines is a valuable research tool for studying and understanding the genetics and function of the genes and processes involved in disease and pest resistance, plant development, primary and secondary metabolism, and response to biotic and abiotic stress (Thomas *et al.*, 2000; Vivier and Pretorius, 2000; Gollop *et al.*, 2002; Mezetti *et al.*, 2002a; Pratelli *et al.*, 2002; Tesnière *et al.*, 2006). However, the lack of high-throughput (HTP) methods for reverse genetics approaches in grapevine functional genomics is a real bottleneck to be overcome in the future (Adam-Blondon *et al.*, 2007). An interesting way is to use transgenic technology and insertion mutagenesis that enhances gene

expression (Pereira, 2000). An Ac/Ds transposon enhancer mutagenesis system has been tentatively applied to grapevine for this purpose (Perl *et al.*, 2000) but is far from being applied routinely. In the future, homology-dependent gene silencing (HDGS) will offer a new tool to shut down the expression of endogenous genes in grapevines. Post-transcriptional gene silencing (PTGS) has been recently suggested in plants using constructs containing repeats that specifically confer aberrant or double stranded RNAs and could likely induce predictable silencing of homologous genes in the host genome (Wesley *et al.*, 2001). However, until now the RNA interference (RNAi) technology has been used in grapevines only for inducing virus resistance (Jardak-Jamoussi *et al.*, 2004) and silencing the berry polyphenol oxidase gene (M.R. Thomas, personal communication). Another HTP technology proposed for silencing genes in grapevines is virus-induced gene silencing (VIGS) that employs virus vectors carrying fragments from the exons of plant host genes that can be introduced by transformation or viral infection into the host and result in the suppression of endogenous gene expression (Baulcombe, 1999). Attempts to use VIGS are currently being investigated at the INRA at Colmar (O. Lemaire and P. Mestre, personal communication).

2. DEVELOPMENT OF TRANSGENIC GRAPES

2.1 Donor, Marker, and Reporter Genes

In grapevine genetic engineering, such as in other crop plants, three types of genes are commonly introduced into the plants; (i) selectable marker genes which are crucial for the development of plant transformation technology because they allow scientists to identify and isolate transformed cells from nontransformed cells and to monitor and select for the transformed progeny, (ii) visual marker genes or reporter genes, which enable direct observation of transformation events and result in a more precise and easier evaluation of various treatments and procedures, and (iii) genes of interest corresponding to the traits being modified.

2.1.1 Selectable marker genes

Until now, approximately 50 selectable marker genes have been used for transgenic plant research or crop development and evaluated for efficiency, safety, scientific applications, and commercialization (Miki and McHugh, 2004). Selectable marker genes can be divided into several categories depending on whether they confer positive or negative selection and whether selection is conditional or nonconditional on the presence of external substrates. The selectable marker genes currently used for grapevine are few and correspond to the first category as they promote the growth of transformed tissue and are conditional on the use of toxic agents, such as antibiotics or less frequently herbicides. All these genes have bacteria as the donor sources.

The neomycin phosphotransferase II (*nptII*) gene confers resistance to the antibiotic kanamycin or other aminoglycoside antibiotics such as neomycin and paramomycin and is the most widely used (see Tables 1 and 2). It is generally placed under the control of the promoter (pNOS) of the bacterial nopaline-synthase gene with the terminator (tNOS) of the same gene. In some cases, it has been used with the manopine synthase promoter (Agüero *et al.*, 2006), with the widely used constitutive 35S promoter from the cauliflower mosaic virus (Olah *et al.*, 2003; Wang *et al.*, 2005; Agüero *et al.*, 2006) or even with the Ubiquitin 11 promoter from *Arabidopsis thaliana* (Vidal *et al.*, 2003). The *nptII* gene has been experimentally fused with reporter genes, such as *uidA* and/or *gfp* (see Section 2.1.2) and placed under the control of a double enhanced

35S promoter (Kikkert *et al.*, 1996; Li *et al.*, 2001; Vidal *et al.*, 2003). Two other selectable marker genes have been used with success in grapevine, the hygromycin phosphotransferase (*hpt*) gene conferring resistance to the antibiotic hygromycin and the phosphinothricin aminotransferase (*pat*) gene conferring resistance to the Basta[®] herbicide. They were generally placed under the control of the 35S promoter with a tNOS terminator (Perl *et al.*, 2004; Bouquet *et al.*, 2006). Procedures and efficiency of selection are different according to the type of marker genes used (see Section 2.3). Though the *nptII* gene product was determined to be safe in the United States and its use permitted in genetically engineered food (Redenbaugh *et al.*, 1994), the use of antibiotic marker genes in potential commercial products has become unacceptable in Europe because of public distrust. Thus, alternative methods of selection for grapevine transgenic breeding are currently under investigation (see Section 3.3).

2.1.2 Visual marker or reporter genes

The bacterial enzyme β -glucuronidase (GUS), which is coded by the *Escherichia coli* gene *uidA* (Jefferson *et al.*, 1987) has been the first and the more extensively used visual marker used in genetically modified (GM) plants in general and in grapevines in particular because of the enzyme stability and versatility allowing histochemical localization and fluorometric quantification at low cost. The major drawback is that the assays are destructive to the plant cells. A feature of GUS is its capacity to generate fusions with other

proteins that extended its usefulness for gene-tagging experiments. In grapevine genomics, it has been used for functional analysis of the resveratrol synthase gene promoter (Schubert *et al.*, 1997) and the dihydroflavonol reductase gene promoter (Gollop *et al.*, 2002). Though the low level of GUS protein from GM plants is not a concern with regard to toxicity or allergenicity (Gilissen *et al.*, 1998), its use in commercial transgenic cultivars is prohibited in Europe.

The luciferase enzyme (LUC) that is coded by the firefly *Photinus pyralis* gene *luc* and uses luciferine as a short-life substrate is a visual marker that offers several advantages including the capability of monitoring gene expression patterns nondestructively in real time with great sensitivity (Ow *et al.*, 1986). However, probably because of substrate cost and the need of specific detection equipment, LUC has been used infrequently in grapevine for promoter functional analysis via transient transformation (Torregrosa *et al.*, 2002b; Verriès *et al.*, 2004). The same group stably introduced *VvAdh2* or 35S promoter fusions to *luc* into grapevine plants and observed strong *luc* expression (P. Chatelet and L. Torregrosa, personal communication).

The green fluorescent protein (GFP) from jellyfish (*Aequora victoria*) has become a powerful reporter as it allows visualization of gene expression in living tissue in real time without invasive procedures such as the application and penetration of cells with substrate and products that may diffuse within or among cells. Both advantages provide a significant improvement over *uidA* and *luc* reporter genes. It is now used by many groups and has a low cost (Haseloff *et al.*,

1997; Harper *et al.*, 1999; Stewart, 2001; Hraska *et al.*, 2006). In grapevine, GFP has been used to characterize the activity of three constitutive promoters using a bifunctional fusion marker containing the *gfp* and the *nptII* genes (Li *et al.*, 2001, 2006) and stability of expression (Iocco *et al.*, 2001). It was also used to analyze in transgenic tobacco plants, the promoter of the grapevine *mrip1* gene coding for the Merlot ripening-induced protein 1 (Burger *et al.*, 2006) and currently the promoters of several transcription factors involved in berry development (Fernandez *et al.*, 2007). It is also a very useful tag for monitoring intracellular localization and transport of fusion proteins. GFP is particularly useful to visualize putative transformed events in embryogenic tissues (Torregrosa *et al.*, 2002a; Li *et al.*, 2006) because reading is not hampered by chlorophyll fluorescence and GFP positive cells can be selected and extracted from the remaining tissues without damage. Using *in situ* GFP-assisted selection with a selection agent (Li *et al.*, 2006), it was possible to moderate the level of the selection agent or the length of selection period and reduce the number of false positive or chimeric structures (see below).

2.1.3 Genes of interest

Since the first reports of transformation based on reporter genes and embryogenic cultures, the production of transgenic vines has become routine in private and publically run laboratories, worldwide. Some advanced work continues on the improvement of methods and procedures (Wang *et al.*, 2005; Li *et al.*, 2006), and applications in grapevine genomics are currently developing in some laboratories (Tesnière *et al.*, 2006) but much effort has shifted to the transfer of potentially beneficial genes into rootstock and scion cultivars. Among the latter, fungal or bacterial disease resistance has been of paramount interest, while in rootstocks, virus resistance has been the focus. Although the major objective of many groups is to obtain GM grapevine cultivars adapted to a sustainable and environmental-friendly production system, some projects have also focused on product quality, especially in table grapes and raisins.

Until now, few sequences of *V. vinifera* genes have been introduced into grapevine. They include

the coding sequence of the *Vst1* (*Vitis* stilbene synthase 1) gene (Wiese *et al.*, 1994) that was fused to a fungal-inducible promoter belonging to a class 10 PR (pathogenesis related) gene expressed in alfalfa and introduced in the rootstock 41 B to improve tolerance to *Botrytis cinerea* (Coutos-Thevenot *et al.*, 2001). The coding sequence of the Shakerlike outward rectifying potassium channel SOR was cloned from a complementary DNA (cDNA) library of *V. vinifera* cv. Pinot noir and a dominant negative mutant was introduced into *V. vinifera* cv. Portan for a reverse genetics study (Pratelli *et al.*, 2003). At the same time, the promoter sequence (3 kbp, kilo base pair) of the inward rectifying potassium channel SIRC was fused to *uidA*, introduced into Portan, and showed strong GUS levels in guard cells (Pratelli *et al.*, 2002). The grapevine *VvAdh2* (alcohol dehydrogenase 2) coding sequence (1.3 kbp) was cloned from a *V. vinifera* cv. Danuta genomic DNA library and introduced in the sense and antisense orientation into Portan (Tesnière *et al.*, 2006). The promoter sequence (2.2 kbp) of the *dfr* (dihydroflavonol reductase) gene was isolated from a *V. vinifera* cv. Red Globe genomic DNA library. The 2.2 kbp sequence and deletion fragments of 757 and 265 bp were fused with *uidA* and introduced in *V. vinifera* cv. Superior seedless (Gollop *et al.*, 2002). Recently, some resistance gene analogs (RGAs) were cloned from a cDNA library of a *V. vinifera* × *Muscadinia rotundifolia* hybrid bearing the *Run1* gene that provides complete resistance to the powdery mildew (Barker *et al.*, 2006) and are currently introduced with their own promoters into *V. vinifera* cvs. Portan and Chardonnay (A. Bouquet, personal communication).

However, most genes of interest that were inserted into grapevine come from other plants or other living organisms including animals, fungus, bacteria, and virus. With regard to genes coming from plants, monocots or dicots, a fragment (1.1 kbp) of the coding sequence of the rice chitinase gene (*RCC2*) classified as class I chitinase (Nishizawa and Hibi, 1991) was introduced into *V. vinifera* cv. Neo Muscat and enhanced resistance to powdery mildew and anthracnose (Yamamoto *et al.*, 2000). Genes encoding a class II chitinase, a class II 1,3 glucanase, and a ribosome inactivating protein (RIP) were cloned from barley (*Hordeum vulgare*) and proven to enhance fungal resistance of

tobacco transgenic plants (Jach *et al.*, 1995). They were introduced into *V. vinifera* cvs. Dornfelder and Riesling (Harst *et al.*, 2000) and in the *Vitis* hybrid "Seyval" (Bornhoff *et al.*, 2005). The full-length coding sequence (975 bp) of the *Vr-ERE* gene (eutypane-reducing enzyme) was cloned from a *V. radiata* cDNA library (Guillen *et al.*, 1998) and introduced into the rootstock 110 R (Legrand *et al.*, 2003) and *V. vinifera* cv. Portan (J.-P. Roustan and A. Bouquet, personal communication) in the hope of conferring resistance or tolerance to the Eutypa dieback disease. The use of the *Vr-ERE* gene as an alternative selectable marker using structural analogs of the toxin Eutypin as selection agents are currently being investigated in grapevine (A. Bouquet, M.C. Cutanda, and L. Torregrosa, personal communication), apple, and pear (E. Chevreau, personal communication). The *GNA* gene from the snowdrop *Galanthus nivalis*, encodes a lectin protein that may repel sap-sucking insects such as phylloxera. Before being used in *V. vinifera*, it was experimentally inserted into the rootstocks Freedom, 101-14 and Teleki (Viss and Driver, 1996) but the results of the resistance tests have not yet been published. A gene encoding the iron-binding protein ferritin was cloned from *Medicago sativa* (Deak *et al.*, 1999) and introduced into the rootstock cultivar 110 R (Olah *et al.*, 2004). The coding sequence (1 kbp) of a polygalacturonase-inhibiting protein (PGIP) gene cloned from pear (Stotz *et al.*, 1993) was introduced into *V. vinifera* cvs. "Thompson seedless" and "Chardonnay" and reported to confer some degree of resistance to *Botrytis* and PD (Agüero *et al.*, 2005).

Plant promoter sequences used for grapevine transformation studies include a pathogen-inducible PR 10 promoter from alfalfa (Coutos-Thenot *et al.*, 2001). Perl *et al.* (1994) constructed a synthetic gibberellin (GA)-inducible promoter using a common motif appearing in promoter regions of different GA-regulated plant genes, which were then placed downstream to a truncated minimal 35S promoter. The ovule-specific regulatory regions from the *DefH9* gene of *Antirrhinum majus* was shown to drive the expression of an auxin-synthesis (*iaaM*) bacterial gene conferring parthenocarpic fruit development in tomato and strawberry transgenic plants (Ficcadenti *et al.*, 1999; Mezetti *et al.*, 2002a). This synthetic gene *DefH9-iaaM* was also inserted into table grape cultivars (Mezetti *et al.*, 2002b). The

ubiquitin 3 promoter coming from *A. thaliana* and a signal peptide coming from the pea vicilin protein were used to drive the expression of magainin genes in grapes (Vidal *et al.*, 2003). The flower-specific and developing fruit-specific promoter *Ag15* from *A. thaliana* proved to be efficient in grapevine when fused with the *uidA* reporter gene (Motioike *et al.*, 2002). In contrast the ACT2 promoter from *A. thaliana*, previously shown to be a strong constitutive promoter in this and other species, failed to promote significant expression of a *gfp* reporter gene in grapevine (Li *et al.*, 2001).

Few genes coming from animals, vertebrates and invertebrates, have been used for grapevine genetic engineering. The gene *Shiva-1* encoding the antibacterial immune protein cecropin was cloned from the moth *Hyalophora cecropia* (Xanthopoulos *et al.*, 1988) and introduced into *V. vinifera* cv. Thompson seedless (Scorza *et al.*, 1996) in an attempt to improve tolerance to bacterial diseases. Transformed plants were obtained, but the results of their assessment were not published. More recently, the sequence (72 bp) of the *mag 2* gene encoding a natural magainin was isolated from the skin of the African clawed frog *Xenopus laevis*, fused with a 48 bp signal peptide from the pea vicilin protein (Pang *et al.*, 1992) and placed under the control of the *A. thaliana* ubiquitin 3 promoter. Natural magainins or their synthetic derivatives are small peptides that have broad-spectrum antimicrobial activity, inhibiting the growth *in vitro* of bacteria and fungi including major grapevine pests such as *Agrobacterium tumefaciens* (Li and Gray, 2003). The *mag 2* gene, the synthetic magainin *MS199* gene, and a peptidyl-glycine-leucine gene also isolated from *X. laevis* were introduced in *V. vinifera* cv. Chardonnay (Vidal *et al.*, 2003). Expression of the *mag 2* and *MS199* genes in transgenic lines induced significant diminution of crown gall symptoms. However, only *mag 2* induced measurable symptom reduction but not strong resistance to powdery mildew (Vidal *et al.*, 2006a).

Two genes coming from fungi have been used for grapevine genetic engineering. The gene *suc2* from the yeast *Saccharomyces cerevisiae* coding for an invertase was inserted into table grapes to investigate if an alien invertase expressed in developing grape berries could alter the sucrose level and the accumulation of glucose and fructose, improving the fruit sweetness of early ripening

cultivars (Perl *et al.*, 1994). The gene *ThEn42* encoding an endochitinase from the biocontrol fungus *Trichoderma harzianum* (Hayes *et al.*, 1994) was inserted by biolistics into *V. vinifera* cvs. Merlot and Chardonnay (Kikkert *et al.*, 2000). For Chardonnay, the results of greenhouse and field tests were indicative of a relationship between chitinase expression and reduced incidence and severity of *Botrytis* bunch rot. However, the level of powdery mildew resistance observed did not correlate with chitinase expression and was not substantial enough to warrant further trials (Reisch *et al.*, 2003).

Few bacterial genes have been introduced into grapevine. Truncated *virE2* genes isolated from *A. tumefaciens* strains C58 and A6 and from *Agrobacterium vitis* strain CG450 were inserted into the rootstock 110 R. Transgenic lines with the *virE2* gene from C58 expressed resistance to crown gall, but not transgenic lines with the *virE2* gene from A6 and CG450 (Holden *et al.*, 2003). The *barnase* gene that codes for a ribonuclease of *Bacillus amyloliquefaciens* was introduced into *V. vinifera* cv. Red Globe under the control of a seed-coat-specific promoter and it was claimed to cause ablation of developing seeds resulting in berries having soft seed rudiments but not complete seedlessness (Perl *et al.*, 2003). The *iaaM* gene from *Pseudomonas savastanoi* was inserted into table grapes with an ovule-specific regulator (Mezetti *et al.*, 2002b). The gene encoding the streptavidin protein from *Streptomyces avidinii*, placed under the control of the embryo-specific promoter Tob-RB7, controls the availability of biotin and induced depletion of biotin during early stages of seed development, leading to almost total seed degeneration in transgenic table grapes (Perl *et al.*, 2003).

Due to the problems caused by viruses, most of the donor gene sources reported in grapevine transgenic studies have been of virus origin. Since the first report of resistance to the tobacco mosaic virus (TMV) using transgenic tobacco plants (Powell-Abel *et al.*, 1986), similar results have been obtained for a broad range of viruses in different plant species. Virus-resistant transgenic plants acquire the so called pathogen-derived resistance (Sanford and Johnston, 1985) through the expression of a viral sequence, such as a coat protein (CP), replicase or movement protein genes (Baulcombe, 1996). Viral resistance was obtained

by introducing the grape chrome mosaic virus (GCMV) CP gene into the rootstock 110 R (Le Gall *et al.*, 1994). This success was concomitant with the transformation of the rootstocks 110 R and *V. rupestris* cv. du Lot (Krastanova *et al.*, 1995) with the grape fanleaf virus (GFLV) CP gene. The same plasmid p1660, bearing CP, *uidA*, and *nptII* genes, was used to obtain transgenic plants from the rootstocks 41 B, SO4, and *V. vinifera* cv. Chardonnay (Mauro *et al.*, 1995). Since then, the GFLV CP gene in the translatable or untranslatable form has been inserted with success into a *V. vinifera* cv. Russalka seedling (Golles *et al.*, 2000) and in several other rootstock cultivars such as *V. riparia* cv. Gloire, 3309C and 101-14 (Krastanova *et al.*, 2000). Preliminary screening by graft inoculation *in vitro* and in the greenhouse suggested that some lines were resistant (Krastanova *et al.*, 2000). The GFLV CP gene was inserted equally into *V. vinifera* cultivars in sense and antisense orientation (Gambino *et al.*, 2005) or in translatable, untranslatable, and truncated forms (Maghuly *et al.*, 2006). But CP was not the only one gene from GFLV to have been used in grapevine. The GFLV replicase, proteinase, and movement protein genes were inserted in the rootstocks 110 R and 41 B (Barbier *et al.*, 2000; Mauro *et al.*, 2000; Valat *et al.*, 2006). With regard to other nepoviruses, the tomato ring spot virus (TomRSV) CP gene was inserted into *V. vinifera* cv. Thompson seedless (Scorza *et al.*, 1996). The introduction of the arabis mosaic virus (ArMV) CP gene into grapevine was also attempted (Golles *et al.*, 2000; Spielmann *et al.*, 2000) but transgenic *V. rupestris* plants expressing ArMV CP gene did not accumulate the CP at a detectable level and were not protected against ArMV infection under green-grafting conditions, whereas accumulation of the CP and protection was observed in *Nicotiana benthamiana* transgenic plants (Spielmann *et al.*, 2000). With regard to other grapevine viruses such as closteroviruses and vitiviruses, the grape leafroll-associated viruses 2 and 3 (GLRaV-2 and -3) CP gene was inserted in sense and antisense orientation into several rootstocks, such as *V. riparia* cv. Gloire, 3309 C, 101-14, and 110 R (Krastanova *et al.*, 2000) and the genes coding for the CP of grapevine virus A (GVA) and B (GVB) associated with different syndromes of the rugose wood complex, were inserted into a *V. vinifera* cv. Russalka seedling (Golles *et al.*, 2000). The gene

coding for the movement protein of GVA was inserted in sense and antisense orientation into the table grape cultivar Superior seedless and the rootstock *V. rupestris* cv. du Lot (Martinelli *et al.*, 2000, 2002).

The 35S promoter from cauliflower mosaic virus has been extensively used in grapevine transformation studies. Promoters derived from the subterranean clover stunt virus have been tested and found to be similar to the califlower mosaic virus (CaMV) 35S and NOS promoters (Thomas *et al.*, 2000). More recently, a bidirectional promoter with duplicated enhancer derived from the cassava vein mosaic virus (CsVMV) was found to have higher activity than the corresponding promoter from CaMV in transgenic grapevines (Li *et al.*, 2001).

2.2 Methods of Transformation Employed

The first experiments of *in vitro* grapevine inoculation by *Agrobacterium* were reported by Hemstad and Reisch (1985). By inoculating *Vitis* interspecific hybrids shoots with *A. tumefaciens* (C58C1 pTi37) or *Agrobacterium rhizogenes* strains (A4 and K37), these authors could induce the formation of galls and putative transformed roots, but the insertion of transfer DNA (T-DNA) in the tissues and organs recovered was not investigated. *Agrobacterium*-mediated transformation is the most widely used system to introduce transgene in grapevine.

2.2.1 *Agrobacterium*-mediated transformation

2.2.1.1 *Transgenic roots obtained with A. rhizogenes*

Gribaudo and Schubert (1990) were the first to report the production of properly characterized grapevine transformed roots. Using the wild type 8196 *A. rhizogenes* strain, they obtained roots of several *V. vinifera* cultivars exhibiting the right hairy root phenotype and producing opines. The same year, Guellec *et al.* (1990) were the first to obtain grapevine transgenic organs coding for engineered transgenes. Inoculating plantlets of *V. vinifera* cv. Grenache with C58C1 pRi 15834

or both pRi 15836 + pGV1850::1103, a co-integrate vector bearing the kanamycin resistance gene, they established hairy roots producing neomycin phosphotransferase protein (NPTII) but no plants were regenerated. Surprisingly, Nakano *et al.* (1994) introduced the *nptII* and *uidA* genes into embryogenic cultures of *V. vinifera* cv. Koshusanjaku with an *A. rhizogenes* strain and regenerated plants expressing these genes but exhibiting altered phenotypes, likely due to the presence of the oncogenes from the nondisarmed pRi. Similarly, Shimizu *et al.* (1994) reported in an abstract the successful adventitious shoot regeneration from Ri plasmid-induced hairy roots and the development of transgenic grapevines but no additional publication resulted. Torregrosa and Bouquet (1997) used *A. rhizogenes* and *A. tumefaciens* co-transformation to obtain grapevine hairy roots producing the GCMV CP but the regeneration of plants was not achieved. Despite problems with plant regeneration, this system is very useful for producing material for root pathogen studies or to investigate the effect of transgene expression on root metabolism and development (Lupo *et al.*, 1994; Torregrosa and Bouquet, 1997; Franks *et al.*, 2006). Moreover, the possibility to use the transgenic hairy roots as rootstocks (Torregrosa and Bouquet, 1997) provides an opportunity to study the interaction between a transgenic root system and a wild-type scion.

2.2.1.2 *Transgenic plants obtained with A. tumefaciens*

Though Baribault *et al.* (1989, 1990) obtained transformed cells of *V. vinifera* cv. Cabernet Sauvignon expressing *nptII* and shoots expressing GUS, the successful regeneration of transgenic grapevine plants was first achieved by Mullins *et al.* (1990), using *A. tumefaciens* LBA4404 bearing pCGN7320 encoding *uidA* and *nptII* genes. These authors observed GUS positive adventitious buds of *V. vinifera* cv. Cabernet Sauvignon and Chardonnay, but they could regenerate transgenic shoots only from hypocotyls from somatic embryos of *V. rupestris*. Since then a number of different genotypes, including *Vitis* species and hybrids (rootstocks) and several commercially important *V. vinifera* cultivars have been transformed (for review, see Kikkert *et al.*,

2001; Perl *et al.*, 2004). Currently, the most widely used system consists of the co-culture of disarmed *Agrobacterium* strains containing binary vectors with grapevine somatic embryogenic callus or cell suspensions (Perl *et al.*, 2004; Bouquet *et al.*, 2006). Embryogenesis has been induced from a range of organs: zygotic embryos, leaves, ovaries, and stamens (Martinelli and Gribaudo, 2001; Torregrosa, 1995), with stamens being the most reliable organ.

Using embryogenic competent explants, the system includes several steps:

1. Initiation and propagation of embryogenic tissues on solid or in liquid cultures.
2. Pretreatment of tissues to improve susceptibility to *Agrobacterium* (optional, see below).
3. Co-culture of the bacteria and grapevine tissues.
4. Selection and multiplication of transformed cells.
5. Differentiation of transformed embryolike structures.
6. Conversion of putatively transformed somatic embryos into plantlets.

Tissues produced by explants cultured on semi-solid embryogenic induction media are generally heterogeneous and contain friable structures with various rates of growth mixed with differentiating somatic embryos. After several cycles of subculture and selection on semi-solid media, the yellowish-friable tissues are preferably selected because this type of callus, formed of proembryogenic clusters, is very stable and allows easy long-term maintenance either on semi-solid or liquid media (Figure 1a). However for some cultivars, this type of callus is not very stable on semi-solid media and another type of tissue dominates composed of embryogenic cell clusters (generally in the core in contact with the medium) surrounded by embryolike structures and embryos at different stage of development (from globular to immature torpedo). Some authors have named the first type of callus, type I and the second one, type II. It is easy to shift from type I to type II by changing plant regulator balance, reducing the auxin concentration or replacing a strong auxin 2,4-dichlorophenoxyacetic acid (2,4-D) by a weaker one *b*-naphthoxyacetic acid (NOA) or 1-naphthaleneacetic acid (NAA). It is not clear which kind of callus is more appropriate for

Agrobacterium transformation as the reports are contradictory on this point (Mauro *et al.*, 1995; Perl *et al.*, 1996a; Scorza *et al.*, 1996; Franks *et al.*, 1998; Torregrosa *et al.*, 2002a), probably because of the diversity of the culture conditions and selection strategy (Kikkert *et al.*, 2001). Because type I is more convenient for propagating the tissue but not necessary the best for co-culture with *Agrobacterium*, some preliminary experiments may be required to clarify this point.

Co-cultivating embryogenic callus or suspension with *Agrobacterium* is considered as a general method because it has been a successful method for many genotypes (Iocco *et al.*, 2001; Martinelli and Mandolino, 2001; Perl and Eshdat, 1998; Perl *et al.*, 2004) but efficiency and reliability vary considerably from one genotype to another even between cultivars from the same species. Some steps need modification for some highly recalcitrant *V. vinifera* cultivars, like the seedless grape Danuta (Torregrosa *et al.*, 2002a), the wine grape Pinot noir (Iocco *et al.*, 2001) or *Vitis* hybrid cultivars, like Niagara (Motioike *et al.*, 2002).

As an alternative to the use of embryogenic cultures, several groups have investigated adventitious organogenesis. The system is based on the use of explants that are able to produce adventitious budlike structures (Torregrosa, 1995), i.e. leaves, petioles, stem fragments or somatic embryo fragments. This regeneration process was developed for several grapevine including *Vitis* species (Tang and Mullins, 1990), *V. vinifera* (Colby *et al.*, 1991b), and intergeneric hybrids like *Vitis* × *Muscadinia* (Torregrosa and Bouquet, 1996). Organogenesis competence has to be induced at the time or soon after contact with *Agrobacterium*. Despite much effort, experiments did not succeed in demonstrating the utility of this method for obtaining transgenic plants (Colby *et al.*, 1991a). Recently, Mezetti *et al.* (2002b) reported the regeneration of transgenic plants of table grape cultivars using a system based on intense axillary and adventitious budding induced by high benzyladenine (BA) levels. The key to the procedure was the production of large amounts of meristematic tissue that implies tedious *in vitro* apex manipulations. However, it is difficult to determine the utility of this system for other genotypes as the original work focused on two *V. vinifera* cultivars and there has been no additional report.

Figure 1 Grapevine transformation. (a) Friable embryogenic callus grown on semi-solid medium suitable for *Agrobacterium*-mediated transformation experiments (bar = 100 μ m). (b) Germinating transgenic somatic embryos after transformation (bar = 1 cm). (c) Variegated GFP pattern in the skin cells of postveraison berries. Expression of the *gfp* gene is controlled by the UFGT promoter. (d) A field trial of transgenic grapevines in Australia. Inflorescences are bagged to prevent pollen escape

2.2.1.3 *Agrobacterium* strains

There are three important points that need to be considered when using *Agrobacterium* to mediate transformation; one is in relation to the efficiency of the bacteria to transfer the T-DNA to the host, the second relates to the response of the plant tissue to co-culture with the bacteria and the third is related to the selection procedures.

The *Agrobacterium* strain used in transformation experiments can play a significant role in *Agrobacterium*-host tissue interaction. The chromosomal background is involved in some important features in the attachment between bacteria and the plant cell (Lorence and Verpoorte, 2004). Virulence genes of the pTi or pRi are also important as they support many aspects of the transformation process, i.e., bacteria-host

signaling, transaction on binary T-DNA borders, and supplying the protein machinery of T-DNA transport (Tzfira and Citovsky, 2003). Moreover, during the interaction with *Agrobacterium*, several changes occur in host gene expression leading to various molecular changes, i.e., the production of PR proteins, which may affect tissue development (Ditt *et al.*, 2006).

Several disarmed *A. tumefaciens* biovar 1 strains have shown some efficiency in transferring T-DNA into grapevine; LBA4404 (Hoekema *et al.*, 1983), GV2260 (Deblaere *et al.*, 1985), EHA101 (Hood *et al.*, 1986) and its derivative, EHA105. Grapevine is a natural host for *A. tumefaciens*, but *A. vitis* (previously named *A. tumefaciens* biovar 3) is the most frequently isolated strain from naturally infected grapevines (Burr and Katz, 1983). Compared to *A. tumefaciens*, *A. vitis*

shows unique properties in relation to T-DNA content (*vir* sequences), enzymatic properties, and epidemiology (Schrammeijer *et al.*, 1998; Burr and Otten, 1999). The question of the efficiency of the natural host *A. vitis* is still unresolved (Kikkert *et al.*, 2001) but because of the lack of disarmed strains, little attention was initially paid to the use of this species.

From fragmented shoot apices inoculated with Ag162 (*A. vitis*), Baribault *et al.* (1990) could recover putative transformed buds of cv. Cabernet Sauvignon. Süle *et al.* (1994), studying the effect of *A. vitis* on various *Vitis* genotypes found that *V. vinifera* gives the best response in terms of galling, *vir* gene induction, and GUS activity. Stover *et al.* (1996), who studied the response of several *Vitis* genotypes to CG49 containing p35SGUSINT, found Cabernet Sauvignon to be susceptible to *A. vitis*. Using the *gfp* gene (Haseloff *et al.*, 1997) as a reporter, Torregrosa *et al.* (2002a) compared the initial transformation efficiency of *A. tumefaciens* LBA4404 (Ach5 pTiAch5) and EHA105 (C58C1 pTiBo542), *A. rhizogenes* A4 (A4 pRiA4) and *A. vitis* K252, an octopine limited host range (LHR) Ag57 isolate (Panagopoulos and Psallidas, 1973). K252/*gfp* proved able to transform embryogenic tissues of all genotypes tested and GFP positive embryolike structures were recovered but at a much lower rate than with other strains. From all these studies, *A. vitis* appears competent to transfer the T-DNA from a binary vector to different types of grapevine tissues, including embryogenic cultures, but the efficiency is rather low compared to standard *A. tumefaciens* or *A. rhizogenes* strains.

LBA4404, probably the most widely used vector for grapevine transformation experiments during the 1990s is an efficient vector for transforming *V. vinifera* cultivars (Harst *et al.*, 2000; Yamamoto *et al.*, 2000) or *Vitis* hybrids (Mullins *et al.*, 1990; Martinelli and Mandolino, 1994; Motioike *et al.*, 2002). EHA105 carrying a disarmed supervirulent pTiBo542, which was used in later grapevine studies was shown to be a very efficient and versatile vector for transformation (Scorza *et al.*, 1996; Franks *et al.*, 1998; Perl *et al.*, 2004; Wang *et al.*, 2005; Bouquet *et al.*, 2006). The high transformation efficiency of EHA strains or *Agrobacterium* strains carrying A281-derived plasmids was also observed for other woody plants (Gill *et al.*, 2004).

2.2.1.4 Browning of the plant tissue

During the co-culture or soon after, grapevine tissues subjected to *Agrobacterium* become partially dark, with some cultivars being more susceptible than others (L. Torregrosa and M. Thomas, personal communication). The browning is caused by the preparation and the manipulation of the tissues during co-culture and also by the response to the bacteria. Several strategies have been used to reduce browning and include: preculture on fresh medium (Li *et al.*, 2006) or on activated-charcoal enriched medium (Iocco *et al.*, 2001; Bouquet *et al.*, 2006), addition of antioxidants before, during or after co-culture, like PVP and DTT (Perl *et al.*, 1996b) or DTT alone (Li *et al.*, 2006), reduction of bacteria concentration and washing of the bacterial culture before use (Iocco *et al.*, 2001).

2.2.2 Biolistic-mediated transformation

The Department of Horticultural Sciences at Cornell University has extensively utilized this technology for grapevine transformation (Kikkert *et al.*, 2004) and established a system based on the bombardment of fine embryogenic suspensions layered onto a filter disk. Biolistic-mediated transformation, also known as gene gun transformation, appears much simpler than *Agrobacterium*-based technology because it avoids some time-consuming steps including the construction of the binary vector, introduction of the vector into *Agrobacterium*, and culture and maintenance of bacterial strains. It is also much more rapid as transformation experiments can start as soon as the expression cassette is cloned inside any plasmid that is maintained in *E. coli*. Also, after transformation, there is no need for expensive bacteriostatic agents to control *Agrobacterium* growth and, because selection of putatively transformed cells can start in liquid culture, the amount of the selection agent can be lowered.

The Cornell team were the first to transform regenerative grapevine structures using this method. Initially, embryolike structures of the *Vitis* hybrid Chancellor expressing GUS were recovered (Hebert *et al.*, 1993) and Kikkert *et al.* (1996) later succeeded in regenerating these structures into nonchimeric plants. The technology was

very efficient for Chancellor as 100 putative transformed embryos could be recovered per bombarded plate but the rate of transformation with a *V. vinifera* cultivar was only 10–30% (Kikkert *et al.*, 2001). These authors reported that as the bombardment was set to higher pressure at a reduced distance, the number of transformation events increased but also cell damage. In order to obtain better transformation rates (number of transformed cells versus number of injured cells) several parameters required optimization for each new line. Attention to detail was also required for DNA coating procedures, microprojectile energy settings, and selection procedures (selection agent type and level). The biolistic method has been successfully used to introduce genes of interest into Chardonnay, an important *V. vinifera* cultivar (Vidal *et al.*, 2003, 2006b). But other groups' experiences with the biolistic method, Franks *et al.* (1998) with Sultana or Soloki *et al.* (1998) with 110 R rootstock, did not result in regenerated transformed plants. The regeneration of transformed plants from 110 R has not been successful. At the present time, for stable transformation followed by plant regeneration, the biolistic method appears more difficult compared to the use of *Agrobacterium*-mediated transformation. In particular, the fine embryogenic cell suspensions required for efficient biolistic transformation is a type of culture difficult to obtain and stabilize for some cultivars, especially as these cultures also have to maintain the capacity to regenerate plants.

A recent development for the gene gun approach is the minimal gene cassette strategy (Fu *et al.*, 2000). This strategy is based on the fact that for a physical method of transformation, no other DNA sequence apart from the expression cassette is needed for transgene integration and expression. Vidal *et al.* (2006b) tested this technology in grapevine comparing the effectiveness of the co-bombarding of two minimal cassettes (one coding for the MS199 antimicrobial peptide and one coding for *nptII*) or corresponding circular plasmids. Starting with the same amount of tissue, 1 year after the bombardment, they respectively recovered 16 and 28 Chardonnay plants from the mix of minimal cassettes and the mix of the corresponding plasmids. Several plants in both treatments expressed the transgenes. This technology appears very promising to produce

plants containing only sequences of agronomical interest.

2.2.3 Transient transformation methods

Grapevine protoplast technology has been reviewed by Papadakis *et al.* (2001). Compared to other plants, grapevine protoplasts are recalcitrant to propagation and regeneration (Papadakis *et al.*, 2005) possibly due to special features of oxidative metabolism. Wall-less cells are suitable material for experiments based on a single cell design and allow the introduction of DNA or viruses into grapevine plant cells by either electroporation (Valat *et al.*, 2006) or polyethylene glycol (PEG) treatment (Jardak-Jamoussi *et al.*, 2002). Brehm *et al.* (1999) transiently expressed fusions of stilbene synthase promoters to *uidA* in grapevine protoplasts to study the effect of fungal cell wall elicitors on transcription activity. Transient transformation of grapevine protoplasts was also reported by Jardak-Jamoussi *et al.* (2002) who incubated protoplasts in the presence of PEG and the plasmid pB1426 carrying the *uidA* and *nptII* genes, but no transformed tissues or organ were regenerated. Plants regeneration from grapevine protoplasts has been reported only once using embryogenic cultures as donor tissue (Reustle *et al.*, 1995).

Undifferentiated cell suspensions (Torregrosa *et al.*, 2002b) are another suitable tissue for transient approaches. Hawker *et al.* (1973) was the first to describe how to initiate a grapevine cell suspension from small pieces of callus. Callus from various explants (berry, petiole, stem) is used as starting material to establish cell suspension cultures. These cultures represent an interesting system to study grapevine secondary metabolism (Decendit and Merillon, 1996) and gene expression (Loulakakis, 1997). The approach was used by Torregrosa *et al.* (2002b) to study the promoters of *Adh* genes from *V. vinifera* and *A. thaliana*. Large differences in promoter activity were observed that corresponded to the *Adh* promoter leader sequence and the type of cell suspension system. Cell suspensions of *V. vinifera* were found more appropriate than those of *A. thaliana* to investigate grapevine *Adh* promoter functioning. Using this system, further research investigated the possible role of *Adh* 3' flanking sequences in transcript regulation

(Tesnière *et al.*, 2005) and the functioning of the *VvAdh2* promoter (Verriès *et al.*, 2004). Serial deletions of the *VvAdh2* promoter were fused to *luc* and transiently introduced into *V. vinifera* cell suspensions that were subjected to aerobic and anaerobic conditions. Reverse GT-boxes, within the proximal promoter region, involved in the response to anaerobic treatment and putative ethylene responsive elements (ERE) participating in the regulation of *Vvadh2*, could be identified. It appears that undifferentiated grapevine cell suspensions appear a more reliable technology for transient gene expression than protoplasts.

However, both types of tissues can be difficult to induce and maintain and *in planta* or *ex planta* direct organ transient transformation could be an alternative technique to circumvent the use of protoplasts or cell suspensions. The most promising methods of organ or plant transient expression use VIGS for repressing a gene (Robertson, 2004) or overexpressing a gene using agroinfiltration (Kampila *et al.*, 1997). VIGS and agroinfiltration are being investigated for grapevine (P. Mestre and O. Lemaire, personal communication), however, these approaches have not yet become standard for grapevine because there have been no protocols developed and published.

2.3 Selection of Transformed Tissues

2.3.1 Selection and regeneration of putatively transformed plants

After co-culture, an important balance between effective selection of putatively transformed cells and the minimization of the inhibitory effects on cell growth caused by the selective agent must be achieved. This balance is important when using *Agrobacterium*-based protocols as grapevine callus is particularly sensitive to browning caused by contact with *Agrobacterium* and general handling (Perl *et al.*, 1996b), releasing phenolic compounds that inhibit the growth of surrounding tissue. In order to determine the optimal level of selection, it is crucial to know the sensitivity of both transformed and nontransformed grapevine tissues to the relevant selection agent(s).

In decreasing order of use, the selectable marker genes used for grapevine transformation are: *nptII*, *hpt*, and *pat* (see Section 2.1.1). Results

with the phosphomannose-isomerase (*pmi*) gene as an alternative selectable marker were not encouraging (Reustle *et al.*, 2003; Kieffer *et al.*, 2004). Two stages in the regeneration process after transformation of embryogenic tissue have to be considered separately; (i) the selection of embryogenic tissues and the production of nonrooted embryolike structures, and (ii) germination of somatic embryos with roots and shoot production. The sensitivity of callus growth and adventitious shoot and root formation to kanamycin was studied by Colby and Meredith (1990) in several cultivars of *V. vinifera* and in *V. rupestris* cv. St. George, to investigate the suitability of kanamycin resistance as a selectable marker for grapevine transformation. The authors concluded that the high kanamycin sensitivity of adventitious shoot formation in grape exceeded that reported for any other plant species and could likely hinder the recovery of transformed plants. Torregrosa *et al.* (2002a) compared the effect of hygromycin, kanamycin, and phosphinothricin on embryogenic callus of three *V. vinifera* cultivars. Among the three selection agents, only kanamycin and hygromycin could significantly reduce growth without inducing major tissue necrosis. According to the genotype and the medium, 1.25–5 $\mu\text{g ml}^{-1}$ of hygromycin or 80–100 $\mu\text{g ml}^{-1}$ of kanamycin was necessary to significantly inhibit callus proliferation. Interestingly, for the same level of necrosis, hygromycin could reduce more callus growth than kanamycin. Some *Vitis* genotypes (Le Gall *et al.*, 1994) are less sensitive to hygromycin than *V. vinifera* and needed higher concentrations of hygromycin (10–16 $\mu\text{g ml}^{-1}$). The *pat* gene was found to be effective by other authors possibly because genotype-dependent effects (Perl *et al.*, 1996b). Peros *et al.* (1998) studying the effect of kanamycin and hygromycin on axillary bud development observed an interaction between the selection agent and genotype. Similar to embryogenic callus, hygromycin appeared more phytotoxic than kanamycin. Furthermore, the toxic effects of both antibiotics were found to be different. Kanamycin induced leaf chlorosis whereas the leaves of plantlets grown with hygromycin became stunted and turned red. Shoot development was completely inhibited at 0.8 $\mu\text{g ml}^{-1}$ hygromycin or 4 $\mu\text{g ml}^{-1}$ kanamycin. Torregrosa *et al.* (2000) evaluated the level of antibiotic resistance conferred by the *nptII* and

hpt genes using grapevine microcuttings bearing both resistance genes. Results showed that despite higher phytotoxicity of hygromycin compared to kanamycin, the transgenic cuttings exhibited a much better tolerance to hygromycin than kanamycin. Because of insufficient resistance levels conferred by the *nptII* gene, some transgenic clones showed poor growth similar to the nontransformed control cutting in the presence of kanamycin.

NptII was the first resistance gene successfully used to obtain transformed grapevine plants (Mullins *et al.*, 1990) or organs (Guellec *et al.*, 1990) and has been used in the transformation of many grapevine genotypes including *V. vinifera* cultivars or *Vitis* hybrids using kanamycin (Mullins *et al.*, 1990; Martinelli and Mandolino, 1994; Franks *et al.*, 1998; Iocco *et al.*, 2001; Torregrosa *et al.*, 2002a; Motioike *et al.*, 2002) or paromomycin (Mauro *et al.*, 1995; Perl *et al.*, 2004; Wang *et al.*, 2005) as the antibiotic. Nevertheless, because *hpt* confers a better level of tolerance to tissues and organ buds of grapevine than *nptII*, hygromycin selection represents a very good alternative to *nptII* (Le Gall *et al.*, 1994; Perl *et al.*, 1996a; Franks *et al.*, 1998; Pratelli *et al.*, 2002; Tesnière *et al.*, 2006).

Because sensitivity to antibiotic selection varies according to the genotype and the stage of development, 5.0–15 $\mu\text{g ml}^{-1}$ hygromycin or 75–150 $\mu\text{g ml}^{-1}$ kanamycin appears adequate for the selection of putative embryogenic structures whereas during regeneration of plants the level of selection could be reduced to 2.5–5.0 and 25–50 $\mu\text{g ml}^{-1}$ for hygromycin and kanamycin, respectively. Recently, Wang *et al.* (2005) showed that paromomycin could replace kanamycin for selecting *nptII* transformed structures of Red Globe. From this experience and from Perl *et al.* (2004), 5–20 $\mu\text{g ml}^{-1}$ paromomycin would appear to be appropriate to select putatively transformed somatic embryos.

2.3.2 Elimination of agrobacteria

Agrobacteria grow on grapevine tissues either on solid or liquid medium. After 48 h co-culture, it is not rare to observe bacteria growing between explants and medium. A few days later, agrobacteria progressively surround

the tissue and the tissue begins to undergo necrosis. To stop bacteria development after co-culture, tissues are carefully washed with a liquid solution often containing high levels of antibiotics (500–1000 $\mu\text{g ml}^{-1}$). After washing, the grapevine tissue needs to be maintained in contact with antibiotics during several subcultures (Perl *et al.*, 2004; Bouquet *et al.*, 2006) to kill the bacteria. A broad range of antibiotics applied alone or in combination can be used to kill the agrobacteria: carbenicillin, cefotaxime (claforan[®]), amoxicillin plus clavulanic acid (augmentin[®]), ticarcillin plus clavulanic acid (timentin[®]), with concentrations ranging between 200 and 1000 $\mu\text{g ml}^{-1}$. But the efficiency of the antibiotic can vary with the commercial supplier and also storage conditions. Most authors tend not to change the supplier when a system is working and try to use fresh, or recently prepared, antibiotic solutions with the first days after co-culture being particularly important. Another factor to be considered is the strain type, with strains such as EHA101 being particularly difficult to eliminate compared to LBA4404 (L. Torregrosa, personal communication). Antibiotics are generally maintained in the media for 2–3 months after co-culture until transfer of regenerative structures to the light for shoot growth.

2.4 Regeneration of Whole Plants

After the initial co-culture, embryogenic tissues are transferred to a selection medium allowing the differentiation of embryolike structures. There are two options for regeneration: (i) maintain embryogenic proliferation with a medium designed for long-term embryogenic maintenance, or (ii) induce embryo development from the embryogenic tissue by reducing auxin levels. The first option has the advantage to amplify the initial transformation events before regeneration of putative transformed embryos but increases the delay for plant recovery (6–12 additional weeks) and also increases the risk to recover multiple plants from the same transformation events. More generally for grapevine, callus is transferred onto a medium without plant growth regulators (Le Gall *et al.*, 1994) or with reduced auxin levels and/or auxin suppressors (Perl *et al.*, 1996b, 2004; Iocco *et al.*, 2001; Bouquet *et al.*, 2006) to encourage embryo differentiation. To avoid excess browning

during the process of embryogenic tissue selection, some authors delay the selection and increase progressively the amount of the selection agent through subculturing (Franks *et al.*, 1998; Perl *et al.*, 2004; Bouquet *et al.*, 2006).

After 2–3 subcultures of the embryogenic culture on regenerative and selection medium, small clusters of embryos are transferred onto plant growth regulator-free medium to encourage embryo development (selection agent being at the maximum level by this stage). Well-developed embryos (torpedo and further) are then transferred onto medium containing benzylaminopurine (2 μ M BAP (6-benzylaminopurine)) and incubated for 7–10 days under light for greening (Bouquet *et al.*, 2006). Developing embryos are returned to plant growth regulator (PGR)-free medium for 2 weeks under low light intensity to achieve embryo elongation and rooting (Figure 1b). This stage of selection is very important to avoid false positives, as nontransformed embryos are generally unable to root in the presence of the appropriate level of the selection antibiotic. Only germinating embryos are processed further. To stimulate caulogenesis of germinating embryos, whole root meristem regions plus cotyledon upper parts are discarded and a cotyledon basal part containing the shoot meristem is deeply scarified (Pratelli *et al.*, 2002). Explants are placed onto BFe2 medium (Torregrosa and Bouquet, 1995) with the meristem region in contact with the medium and incubated under moderate light intensity. At this stage, the level of selection antibiotic can be reduced to 5 μ g ml⁻¹ hygromycin or 50 μ g ml⁻¹ kanamycin. Emerging shoots are subcultured under the same conditions to encourage axillary branching. Shoots are isolated and converted into plants on root-induction medium containing 1 μ M indole-3-acetic acid (IAA) (Bouquet *et al.*, 2006).

The polymerase chain reaction (PCR) is a convenient method to systematically screen all putative transformed lines using DNA extracted from 100 mg fresh material (1–2 small leaves from *in vitro* plantlets). Depending on the experimental design, several clones of each PCR positive line are transferred into 10 cm diameter pots progressively acclimated to greenhouse or glasshouse conditions (Bouquet *et al.*, 2006). The average rate for successful transplanting and acclimatization depends on the variety but is generally higher than 90%. When

the transgenic plants are successfully established in the greenhouse, the stable integration of the gene of interest is confirmed by Southern blotting and further characterization and testing of the plants can start.

2.5 Testing

The stability of transgene expression and inheritance has not been extensively studied in grapevine. Expression stability has been assessed using the reporter genes *gfp* and *uidA* under the control of the constitutive CaMV 35S promoter (Franks *et al.*, 1998; Iocco *et al.*, 2001). These two reporter genes were used to track transgene expression during the transformation process and to confirm that transgene expression was stable. It was observed that while most regenerated plantlets and mature plants maintained a uniform reporter gene expression pattern, up to 35% showed variegated expression (Franks *et al.*, 1998; Iocco *et al.*, 2001). It was suggested that the variegated expression pattern could be due to a number of factors resulting in gene silencing and methylation of introduced transgenes was demonstrated (Franks *et al.*, 1998). Subsequent observations showed that the *gfp* expression pattern of regenerated grapevine plants was maintained under glasshouse and field conditions for more than 6 years (M. Thomas and P. Iocco, personal communication). This indicates that the expression pattern is fixed after plant regeneration and yearly cycles of winter dormancy, pruning, and bud burst followed by new growth do not change the expression pattern. The same gene expression pattern present in leaves was also found to be present in preveraison and postveraison berries. Stable leaf *gfp* transgene expression over 5 years for Sultana (Thompson Seedless) grown under glasshouse conditions has been reported (Li *et al.*, 2006). Variegated *gfp* gene expression in berry skin has also been observed when the promoter was from the *ufgt* (UDP glucose-flavonoid 3-*O*-glucosyltransferase) gene (P. Iocco and M. Thomas, personal communication). The UFGT protein represents the last enzyme in the anthocyanin pathway and results in the red color of berries and wine. It is not clear whether the variegated expression pattern was due to gene silencing effects as previously seen for the CaMV 35S promoter or was representative of cell-specific

activation of the UFGT promoter in the skin cells of postveraison berries (Figure 1c).

Information on the stability of transgene expression over a number of generations for grapevine is lacking due to the long generation times involved and the fact that cultivars are not propagated by seed but by vegetative cuttings. This means that selection of a superior transgenic vine will always be followed by clonal propagation either by tissue culture or vegetative cuttings. However, results from GFP expressing grapevine plants have demonstrated that transgene expression is transmitted to progeny in the expected Mendelian fashion with progeny showing GFP expression (M. Thomas, personal communication).

Phenotypic differences between transgenic vines and the original donor cultivar have been observed. Reported differences relate mostly to changes in leaf shape (Franks *et al.*, 1998; Iocco *et al.*, 2001). The change in leaf shape was also found in plants regenerated from embryogenic cultures indicating that the culture conditions and regeneration procedure were responsible for the new phenotype and not the transformation procedure. The lobed leaf phenotype reported by Franks *et al.* (1998) for transgenic Sultana vines was still present for the same vines even after 6 years growth, however, the leaves on canes that contained bunches had reverted to the typical nonlobed leaf Sultana phenotype (M. Thomas, personal communication). This suggests that the leaf phenotype may be developmentally controlled. A modified flower phenotype was observed for Chardonnay plants overexpressing the MADs-box gene *VvMADS1* (Boss *et al.*, 2003). The flowers showed extended growth of the calyx/sepals that encased nearly the whole cap structure formed by the petals. Fruit development for these transgenic Chardonnay vines was normal and it was suggested that the altered flower morphology may provide some level of resistance to *B. cinerea*, which infects at the flower cap abscission zone during anthesis (Boss *et al.*, 2003). No results on the effect of transgenes on yield and fruit and wine quality have been published for either transgenic rootstocks or scions as field trials spanning many years are required to obtain this information. Existing GM grapevine field trials may eventually provide us with this information.

The observed stability of gene expression over many years, as reported above, indicates that when

commercial plantings of transgenic vines occur the plants in these vineyards can be expected to maintain the phenotype conferred by the transgene for the life of the vineyard, which is usually more than 30 years.

2.6 Specific Regulatory Measures Adopted

There were no commercial plantings of GM vines in 2006 and therefore no specific regulatory measures have been put into place for commercial growing of transgenic vines or for the sale of the resulting fruit and wine. However, a number of experimental field trials have been carried out in different countries under the regulatory guidelines specific to each country and year of planting (Bouquet, 2006). Internet resources listing grapevine field trials include the United States (<http://www.isb.vt.edu/cfdocs/fieldtests1.cfm>), Australia (<http://www.ogtr.gov.au/>), Europe (<http://gmoinfo.jrc.it/>), and the OECD (<http://webdomino1.oecd.org/ehs/biotrack.nsf>). Countries where field trials have been carried out include Australia, France, Italy, Canada, the United States, Chile, and Germany. These field trials have mostly been managed by research organizations, however, a few have involved commercial wine companies in France (Moët et Chandon), Canada (Chateau des Charmes wines), and the United States (Pebble Ridge Vineyards). The traits being investigated are largely covered in Tables 1 and 2 and can also be found on the above Internet sites and range from resistance to pests and pathogens to flowering and improved fruit quality. Of the many field trials initially established only a few were still active in 2006 with Australia, France, Italy, and Chile each having one field trial and the United States having 12 permits for trials that extended beyond 2006. Management of these GM vines also varied between countries. In Australia, procedures were used to prevent pollen and seed dispersal by bagging inflorescences (Figure 1d) and grape bunches while in Germany and the United States such precautions were not required. Public and government concern based on “Frankenwine” negative media reports have resulted in some field trials being terminated prematurely in a number of countries or specific regions within countries. GM vines have also caused past issues in Europe with

European Commission regulations controlling the marketing of vegetative GM material and derived products (Meldolesi, 2001).

The field trial in Germany has provided useful information on pollen flow from transgenic vines to surrounding non-GM vines (Harst *et al.*, 2006). Hermaphrodite grapevine cultivars were generally considered to be self-fertilizing due to the structure of the flower. Using GUS as a marker and pollen traps it was observed that wind blown pollen could travel at least 100 m from the pollen source. The study also looked at the effective distance of pollen travel in the direction the wind was blowing at the time of anthesis as determined by GUS positive seedlings germinated from seed collected from surrounding non-GM vines. It was found that 2% of seeds collected from non-GM vines in a radius of 10 m from GM vines germinated GUS positive seedlings and 2.7% within a 20 m sector. While the study only looked at pollen flow from 36 *uidA* expressing transgenic vines it does provide the first information about the potential for pollen flow in a commercial vineyard situation. The values found within the small area surveyed were above the European Union GM contamination compliance threshold of 0.9%. However, as the authors point out this threshold is only relevant for grapevine seed or seed-derived products and as berry tissue and wine made from it are derived from maternal tissue GM cross contamination by pollen flow may not be a major issue for wine products. In addition, wine is a highly processed product and methods to detect such low levels of contamination in wine do not currently exist.

3. FUTURE ROAD MAP

3.1 Expected Products

Future products can be divided into those that benefit the grower, winemaker, consumer, or the environment. Economic sustainability is the primary driver for grape growers and winemakers and any GM vine that improves productivity, reduces costs, or allows greater product differentiation will have an advantage over existing varieties. But these GM varieties will only be grown if there is a market for the end product. The globalization of the wine industry since the 1980s has also brought into sharper

focus the fickle nature of consumer preferences. The rapid changes in consumer preferences for wine often resemble that of a fashion industry. The factors that influence consumer preferences are many and varied but a large part is due to (i) marketing and media exposure about a particular wine region, wine style or variety and (ii) value for money. Consumers are also becoming more health conscious and aware of environmental issues and these may also have a future impact on what growers and winemakers produce.

The two major long-term issues confronting viticulture are global warming and the use of chemicals to control many pests and diseases in the vineyard. The application of gene technology to produce GM vines that reduce the use of chemicals to control pests and diseases is a high priority in many parts of the world (see Tables 1 and 2) as growers, the environment and the public will all benefit. The identification and positional cloning of a powdery mildew resistant gene (Barker *et al.*, 2005) for transfer into susceptible varieties is in progress and if successful will represent one of the first case studies where a beneficial grape trait is selectively transferred from *M. rotundifolia* to *V. vinifera*. At the present time a perception exists that industry and public acceptance of GM vines and wines may be more forthcoming if gene transfer is limited between closely related genera and species and the powdery mildew resistance gene is one such example. The use of transgenic rootstocks resistant to pests and virus diseases (Table 1) may also find easier industry and public acceptance since it is only the grafted scion that produces the fruit and therefore any fruit product is non-GM. Modeling of global warming (Jones *et al.*, 2005; White *et al.*, 2006) indicates that regions currently producing high quality grapes and wine will experience an increase in temperature and quality may decrease over time. Solutions to this problem are likely to be explored using a GM approach in the future.

Fruit quality traits such as decreased browning (Thomas *et al.*, 2000) of dried grapes and seedlessness of table grapes (Perl *et al.*, 2003) have been investigated with some success. No reports describing wine made from grapes modified for quality traits have to date been published. The recent discovery that tartaric acid in grape berries is synthesized from vitamin C (DeBolt *et al.*, 2006) opens up the possibility to genetically modify this

process to produce berries and wine with high levels of vitamin C.

The development of future GM grape varieties and products will largely depend on public research for the foreseeable future. This is due to the long period of time (10–25 years) required to develop new GM plants and evaluate the fruit and wine from replicated field trials in different environments, making it an unattractive investment for biotechnology companies. The current concern in many regions of the world about GM products has also reduced investment enthusiasm of wine companies. However, the advantage of the long period required for field evaluation is that all public concerns about GM products will have been addressed through market acceptance of other GM-derived products from other crop species by the time grapes or wine from GM vines are ready for marketing.

3.2 Risks and Concerns

Despite the potential benefits of this new technology to improve the reliability and quality of the world food supply, public and scientific concerns have been raised about the environmental and food safety of GM crops (Hails, 2000). It is feared by some sectors of society that DNA technology will harm people by undesired impacts on health and the environment. In Europe, consumer acceptance of commercial DNA technology plant products seems further away than ever, especially for grape products. Current discussions in western countries mainly focus on GM food and consumer safety. This topic has been reviewed in depth (Kuiper *et al.*, 2001). To some extent, this has diverted public attention away from ecological and environmental concerns about the impact of growing GM crops. With respect to the use of gene technology for grapevine improvement, the public concern is minimal since field experiments are very few. The issue is likely to come before consumers when a grape-derived commercial product is being considered for market release. As this will not occur for quite a few years the intervening years offer an opportunity to debate rationally the advantages and disadvantages of transgenic grapevines on human health, environmental health, and economic health at a regional, national, and global level.

3.2.1 Impact of GM grapevines on health

The safety aspects of the current products of grapevine growing, wine, table grapes, and raisins have always been based on long-term pragmatic experience that started many centuries, if not millenarians ago. The safety assessment of grapevine cultivars obtained from conventional breeding has primarily been based on limited analysis of known macro and micronutrients, antinutrients, and toxicants. Products with unusual tastes or harmful levels of specific compounds have been generally rejected from breeding programs, but sometimes rejection followed only after their release on the commercial market. That was the case in the beginning of the 20th century for some American interspecific hybrid varieties with low and still controversial levels of toxic methyl alcohol in their wines. An interesting example of wine market manipulation and associated trade barriers occurred with the ability to identify anthocyanin diglucosides. Though no scientific data support a possible harmful effect on consumer health, the presence of anthocyanin diglucosides in the berry skins and the wines of most French–American interspecific hybrids was an effective way to distinguish these hybrids from the *V. vinifera* cultivars and helped to eliminate them from the French market after the 2nd World War through planting regulations. These interspecific hybrids were more productive and had better disease tolerance than the original *V. vinifera* cultivars but at the time there was a significant oversupply of wine in France. Industry marketing, assisted by government, promoted low yielding traditional *V. vinifera* cultivars as producers of better quality wine and this perception soon dominated French thinking and spread to the rest of the world. At the end of the 19th century, the success of grafting *V. vinifera* cultivars onto American rootstocks resistant to Phylloxera was delayed for a long period due to baseless fears that some compounds toxic against the aphid, and possibly humans, could potentially be transferred from the roots to the scion and the grapes (Pouget, 1990). This suspicion was often reinforced by some temporary regulations in France that were in hindsight harmful, delaying adoption of best practice methods, and represented early examples of untoward application of the precautionary principle with regulations

based on perception rather than scientific facts.

Safety assessment of GM grapevine cultivars should be carried out on a case-by-case basis, using the concept of substantial equivalence developed from the idea that existing foods can serve as a reference for comparing the properties of foods derived from GM plants. But consensus on practical application of this principle should be further elaborated, particularly with respect to the detection and characterization of unintended effects, such as disruption, modification, or silencing of active genes or activation of silent genes, which may result in the formation of either new metabolites or altered levels of existing metabolites. In the future, the development and validation of new strategies such as a targeted (compound-specific) approach, or nontargeted (profiling) approach based on DNA microarray technology, proteomics, and metabolomics should offer adequate answers (Kuiper *et al.*, 2001). However, it should be emphasized that the occurrence of unintended effects is not specific for genome modification through DNA technology. It also occurs frequently in conventional breeding, but the effects are usually easier to identify when they concern morphological characteristics rather than biochemical pathways.

For GM grapevines, three scenarios are envisioned in which the product (wine or fruit) would be (i) substantially equivalent, (ii) substantially equivalent except for the inserted trait, or (iii) not equivalent at all. An example of the first scenario would be virus (GFLV) resistance induced in a transgenic rootstock by expression of viral CP or movement protein genes (Valat *et al.*, 2006). Even if proteins derived from the inserted genes move toward the scion and the berries, the wine will not be different from a wine obtained with naturally GFLV infected grapevines. The second scenario, likely the most frequent, could be illustrated by the insertion of genes encoding PR-proteins such as chitinase (Yamamoto *et al.*, 2000), antimicrobial peptides such as magainin (Vidal *et al.*, 2006a), PGIPs (Agüero *et al.*, 2005), or lectins such as GNA (Viss and Driver, 1996) in *V. vinifera* scions or rootstocks cultivars to protect them against fungal and bacterial diseases or pests. The potential toxicity of GNA lectin has been reported (Ewen and Pusztai, 1999) even if the conditions

of the test were controversial. Furthermore, a number of known plant-derived allergens are PR-like proteins (Niskanen and Dris, 2004). Thus, the potential allergenic or toxic features of newly introduced proteins have to be carefully evaluated. Furthermore, it should be noted that overexpressing PR-proteins in genetically modified grapevines will lead to increase protein-haze formation and risks in wine turbidity, whereas attempting to remove the PR-proteins from wines by silencing their expression in grapes may increase plant susceptibility to pathogens (Ferreira *et al.*, 2004). The safety assessment of selectable marker genes used in transformation is not specific to grapevine. Health aspects of marker genes encoding resistance to antibiotics have been largely dealt with, and there is a general agreement that newly expressed proteins do not show any risk of toxicity or allergenicity and that horizontal transfer of antibiotic resistance genes from plants to microorganisms residing in the human gastrointestinal tract is unlikely to occur, given the complexity of steps required for gene transfer, expression, and efficacy. Nevertheless, considering the public concern with existing problems with drug-resistant bacteria in human health, transformation technologies that do not result in antibiotic resistance genes, for instance use of alternative marker genes or gene excision methods, have been promoted in some cases (see Section 3.3). The third scenario could also be illustrated by modifications to characteristics of the berry induced for instance by the insertion and overexpression of the yeast invertase gene *SucII*, which aimed to change the ratio of fructose/glucose (Perl *et al.*, 1994) or by silencing the polyphenol oxidase (PPO) gene to produce light colored and low browning Sultana raisins after drying (Thomas *et al.*, 2000). In the past decade, progress has been made with respect to the identification and characterization of berry and wine constituents that may exert beneficial and/or adverse effects on human health. Several compounds have been identified with positive effects on the incidence of cardiovascular diseases (see Section 1.3). The overexpression of some compounds, such as resveratrol, could be interesting (Jeandet *et al.*, 2002). But beneficial compounds may also exert adverse effects, depending on the amount, conditions, and the presence of other agonists or antagonists, and

adequate safety assessments would need to be done.

3.2.2 Impact of GM grapevines on the environment

The ecological probabilities of harm attributed to the release and use of GM plants focuses on the invasion or modifications of ecosystems due to potential weediness, spread of transgenes by either vertical (outcrossing) or horizontal gene flow, secondary ecological impacts such as effects on nontarget or beneficial insects or undesired consequences on soil microbial communities, occurrence of super pests or diseases due to the “breaking down” of the introduced resistance genes, and loss of biodiversity. All these potential risks have been reviewed in depth (Conner *et al.*, 2003). With regard to GM grapevines, some are more important than others.

3.2.2.1 Potential “weediness” of GM grapevines

The ability of grapevines to escape from cultivation and revert to a wild and “weedy” condition alongside neglected vineyards is well known in countries with an old viticulture tradition. This event is more frequently observed with rootstock cultivars of recent origin. Indeed the ability of *V. vinifera* cultivars to revert to a wild condition is less common and may be related to their lower fitness compared to interspecific rootstock hybrids. The emergence of GM “weedy types” of *V. vinifera* could also be associated with chance hybridization with wild populations. For transgenes conferring resistance to herbicides, pests, diseases, and environmental stress, it can be suggested that this may result in increased fitness, survival, and spread. But gene flow between GM vine cultivars and wild vines is likely to be very low in Europe since there are very few remnant wild populations of *V. vinifera* spp. *sylvestris* (Arnold *et al.*, 1998; This *et al.*, 2006) left as a result of the diseases and pests introduced into Europe from America. This *et al.* (2001) did not find any trace of gene exchange in France between a local wild population and the cultivars growing in the vicinity. However, the situation could be different in the United States where large populations

of wild *Vitis* species are still observed, and the occurrence of gene exchange with *V. vinifera* cultivars has been historically proven (Tukey, 1966). For this reason, it is recommended to avoid using herbicide resistance genes as selectable markers and to evaluate carefully the benefits and drawbacks of breeding GM vines resistant to herbicides (Levenko and Rubstova, 2000).

3.2.2.2 Unintended effects on soil-borne microbial communities

Soil is a highly complex ecosystem of primary importance in nutrient cycling that influences primary production and vegetation dynamics. Furthermore, soil interaction with microbial populations of species with antagonistic properties (e.g., pseudomonads and *Trichoderma*) is a key factor in sustainable agriculture. Soil-borne microorganisms, accounting for >80% of the total biomass (excluding roots) are generally heavily exposed to GM plant material, either through root exudates, leaf shedding, or decomposition. Thus, investigating relevant effects of GM plants on soil-borne microbial communities is a major challenge for the future. Glandorf *et al.* (1997) reviewed the effects of GM plants expressing a range of antimicrobial proteins for plant pathogen control, such as chitinases and glucanases, on saprophytic soil microflora. In some cases, changes in the populations of bacteria, fungi, or soil invertebrates have been detected, even though no direct toxicity to the organisms has ever been demonstrated, and the effects can differ according to the plant or the transferred gene requiring assessment on a case-by-case basis (Kowalchuk *et al.*, 2003). Though the GM crops examined thus far appear to have little or no effect on crucial soil organisms and detected effects have been minor compared with other “normal” sources of variation, it may be necessary to have a system in place to screen for unwanted nontargeted effects. However, it should be noted that this has not been done with conventionally bred cultivars or those obtained by mutagenesis. In grapevine, there are considerable gaps in our knowledge on the role of soil-borne microbial communities. Arbuscular mycorrhizal fungi are an important group of beneficial soil microbes that form mutualistic symbioses with grapevines. Grapevine not only responds positively

to colonization (Bavaresco *et al.*, 2000; Linderman and Davis, 2001) but may also suffer in the absence of mycorrhizae (Menge *et al.*, 1983). The role of the grapevine rhizosphere bacteria is also likely significant (Waschkies *et al.*, 1994; Compant *et al.*, 2005).

3.2.2.3 Unintended effects on berry microflora

More is known about the microbial communities that develop on the berry skins. *S. cerevisiae* is by far the best-known yeast strain colonizing ripe berries under natural conditions. The natural pattern of distribution of populations of this yeast has not been clearly established, though many authors suggested that *S. cerevisiae* coexists initially with many other types of yeast on the surface of grape berries, and becomes predominant as the fermentation proceeds (Pretorius, 2000). An ecological study has shown that these yeast floras remain unchanged during successive years in the same vineyard, but vary from one region to another (Frezier and Dubourdiou, 1992). It cannot be excluded that the use of grapevines genetically engineered for disease resistance against fungi or bacterial diseases might cause significant differences in yeast ecology. For instance, the role of endopolygalacturonase was clearly demonstrated in the interactions between colonizing yeasts and grapevines (Gognies *et al.*, 2006) and GM cultivars expressing PGIP could likely alter these interactions. Kim *et al.* (2004) reported that strains of *S. cerevisiae* show different responses to eutypinol, a secondary metabolite produced by the degradation of eutypine, which is implicated as the main phytotoxin from *Eutypa lata*, the fungal disease causing the symptoms of “dying-arm disease”. It cannot be excluded that GM grapevines expressing the *V. radiata*—ERE (Legrand *et al.*, 2003) might modify the distribution of yeasts in favor of strains more tolerant to inhibition of mitochondrial respiration. Changes in wild yeast on berries as a result of an introduced gene is likely to have little effect during wine making as in most cases commercially available yeast strains are added for fermentation. However, it would be prudent for wine making and wine quality assessment to be carried out on grapes harvested from GM vines

prior to commercialization to alleviate concerns oenologists and others may have.

3.2.2.4 Evolution of viral populations

Environmental safety issues have been raised on the potential hazards related to the release of transgenic plants containing virus-derived genes (Tepfer, 2002). In grapevine, the two major concerns are (i) the risk of heterologous encapsidation of RNA in particles composed of CP of another virus and thus the risk to modify the vector specificity (Belin *et al.*, 2001; Andret-Link *et al.*, 2004), and (ii) the risk of genetic recombination between viral transgene transcripts and RNAs from viruses that infect transgenic plants and thus the risk of plant-to-virus gene flow. With regard to the risk associated with the largely used virus-derived CaMV 35S promoter, it has been treated in more detail elsewhere (Hull *et al.*, 2000).

It was first shown in the 1970s that plants infected by two related viruses could result in various forms of heterologous encapsidation (Rochow, 1970). This can in some cases affect viral transmission (Bourdin and Lecoq, 1991). Heterologous encapsidation has been observed in transgenic plants expressing a CP gene from several different viruses (Lecoq *et al.*, 1993; Tepfer, 2002). For grapevine, changes in vector specificity might be possible if a viral RNA of ArMV (transmitted by *Xiphinema diversicaudatum*) is encapsidated by a transgene-encoded CP of GFLV (transmitted by *X. index*). ArMV and GFLV are two distantly related viruses that cause a single disease phenomenon, the grapevine infectious degenerative disease called “court-noué”. The genome of ArMV has segments of sequence similarity common to the genome of GFLV (Loudes *et al.*, 1995), with amino acid comparisons between the proteins encoded by the RNAs of the two virus showing 75% identity (Wetzel *et al.*, 2004). Occurrence of heterologous encapsidation has never been observed in grapevine, either in greenhouse experiments or in field tests, but if there was any potential risk, it could be eliminated easily through modification of the CP gene (Jacquet *et al.*, 1998).

Along with mutation, genetic recombination is considered to be an essential source of variability

for viral genomes and thus play a key role in their evolution (Roossinck, 1997; Worobey and Holmes, 1999). Among many examples, experimental evidence obtained by Le Gall *et al.* (1995) showed template switching in the 3' untranslated region of pseudorecombinants constituted by RNA-1 of GCMV (*Grapevine chrome mosaic virus*) and RNA-2 of TBRV (*Tomato black ring virus*). There is strong evidence for recombination in transgenic plants expressing CP genes (Greene and Allison, 1994; Aaziz and Tepfer, 1999) and its potential effect on virus evolution has been discussed (Rubio *et al.*, 1999). In grapevine, Vigne *et al.* (2004b) screened for the presence of GFLV recombinants in 190 transgenic plants belonging to 18 lines of the 41 B rootstock expressing the GFLV CP gene and 157 nontransgenic plants. Their survey indicated that transgenic grapevines did not promote the emergence of viable GFLV recombinants to detectable levels in any of the two experimental field sites during the trial period nor did they affect the molecular diversity of indigenous GFLV populations. No GFLV variants from the field had features typical of strain F13 from which the CP transgene was derived.

The role of the 3' untranslated region of viral RNA in the recombination of grapevine nepoviruses (Le Gall *et al.*, 1995) has previously been mentioned. In transgenic *Nicotiana benthamiana* expressing the CCMV (*cowpea chlorotic mottle virus*) CP, the deletion of this 3' untranslated region has been shown to reduce or even abolish the recovery of recombinant viruses (Greene and Allison, 1996). In grapevine, the results of Vigne *et al.* (2004b) do not support the involvement of this region in the emergence of viable recombinants, since the transgenic plants contained the complete 3' untranslated region of GFLV RNA-2 (Serghini *et al.*, 1991) and expressed transgene transcripts. This may be explained by low transgene expression in the 18 transgenic grapevine lines with steady state accumulation of transgene messenger RNA (mRNA) orders of magnitude lower than GFLV RNA-2 in infected plants. It should be noted that in the grapevine survey several variants were identified in nontransgenic plants located outside the experimental field site, and the study of their genetic structure showed that heterogeneous populations of GFLV variants in a single vine are likely to result from mixed infections due to

repeated transmission of individual variants by viruliferous nematodes (Vigne *et al.*, 2004a; Vigne *et al.*, 2005). There is apparently strong sequence stability of the GFLV CP gene and the same low degree of diversity was observed among variants in the Champagne region, several European countries, the United States, and China. Thus, it is unlikely that the possible use of transgenic plants in the future will modify this natural variability. The potential problem of recombination between viral and plant genomes is complicated by the recent finding that sequences homologous to those of the nonretro RNA virus PVY (*Potato virus Y*) are integrated into the genome of several grapevine cultivars (Tanne and Sela, 2005). The hypothesis advanced was that the viral RNA recombined with a retrotransposable element, with the product subsequently inserted into the host cell genome as a "native transgene".

To the best of our knowledge, the study of Vigne *et al.* (2004b) is the first and only safety assessment study of recombination with transgenic grapevines expressing a virus-derived gene under field conditions of heavy disease pressure but low, if any, selection pressure against recombinant viruses. The likelihood of recombination within transgenic plants expressing virus-derived genes should be limited if the plants resist viral infection. Conversely, the probability of recombination occurring may increase if transgenic plants expressing virus-derived genes are susceptible to virus infection. The majority of the 18 transgenic grapevine lines tested in the study was susceptible to GFLV infection in vineyard, and though the risk assessment studies of viral recombination need to be followed up over the lifetime of the vineyard, the results obtained by Vigne *et al.* (2004b) under these conditions confirm earlier predictions by Falk and Bruening (1994) who hypothesized that the "potential benefits of engineered resistance genes far outweigh the vanishing small risk of creating new and harmful viruses in significant excess over those being created by natural processes."

3.2.2.5 Impact of GM grapevines on biodiversity

When considering the impact of transgenic plants on biodiversity, it is worthwhile distinguishing

between the biodiversity at large and the biodiversity associated with agricultural practice, which is generally referred to as “agrobiodiversity”. In current-day agriculture, agrobiodiversity is the result of a long process of plant domestication, the establishment of landraces and the deliberate breeding of new cultivars. In viticulture, natural calamities during the 18th and 19th centuries and economic or commercial constraints and regulations during the 20th century (see Section 1.5) have considerably narrowed the varietal basis of world wine production (Bouquet and Boursiquot, 1999). In the future, planting of transgenic cultivars with improved cultural or technological qualities may further reduce the number of available cultivars and thus contribute to worsen the narrowing of the genetic diversity of the cultivated grapevine. Transgenic cultivars would also reduce the level of clonal variability, since in most cases only a single clone will be transformed. But this situation will not be different from that of new cultivars obtained by conventional breeding, since these are typically monoclonal. A solution might be found in the use of somaclonal variation (Larkin and Scowcroft, 1981; Karp, 1991; Torregrosa *et al.*, 2001) that is currently being investigated in France to restore, amplify, or induce clonal variability in traditional or new cultivars (Torregrosa *et al.*, 2001).

3.3 Expected Technologies

The standard procedure for grapevine transformation at the present time is to first initiate embryogenic cultures and then transform these either by *Agrobacterium* or biolistics with plant regeneration occurring by somatic embryogenesis. The process is laborious and months are required to first establish embryogenic cultures followed by many more months after transformation before the first plants are regenerated (Iocco *et al.*, 2001; Bouquet *et al.*, 2006). While transgenic plantlets can be obtained in as little as 18 weeks post transformation (Iocco *et al.*, 2001), it usually requires a year or more to obtain greater than 100 transgenic plants from independent transformation events. Additional years are then required to evaluate genetic modifications affecting flowering or fruit due to the reproductive biology of the grapevine. Some

cultivars, such as Sultana, do not flower under glasshouse conditions and even more amenable cultivars such as Chardonnay still have flowering problems under glasshouse conditions. In most cases this necessitates field plantings of transgenic vines to properly evaluate flowering, yield, fruit development and quality. A typical experiment evaluating yield and fruit from 100 transgenic plants might require a minimum of 2 years from embryogenic culture initiation to regenerated plants followed by a 5-year field trial to collect data over a number of seasons. In practice, the process is actually longer and can require 8 or more years as harvests over three seasons are required and not all plants flower after 2 years in the field (M. Thomas, personal communication).

New technologies and plant material that can reduce the time from genetic modification to evaluation of the modified trait will be of greatest benefit to grapevine transgenic research. The use of *A. rhizogenes* for producing transgenic root cultures appears to show some promise for evaluating modified root traits (Lupo *et al.*, 1994; Torregrosa and Bouquet, 1997; Franks *et al.*, 2006). The use of *Agrobacterium* infiltration techniques for tobacco leaves (Schob *et al.*, 1997) and tomato fruit (Orzaez *et al.*, 2006) might have application for grapevine but there are no published reports for grapevine. The same situation is true for VIGS methods (Baulcombe, 1999) that use virus vectors introduced by transformation or viral infection with no reports of success with grapevine. The use of rapid flowering grapevine genotypes (Boss and Thomas, 2002) for stable transformation studies might also find application in reducing the time from plant regeneration to fruit evaluation. New stable transformation and regeneration methods that avoid the use of embryogenic cultures would also be an advantage but as discussed above (Section 2.2.1.2) the successful report by Mezetti *et al.* (2002b) using adventitious budding tissue has certain limitations.

It is also expected that in the future new selectable markers and vectors more acceptable to regulators of GM plants and products will be developed that benefit all plant transgenic research. The gene encoding the streptavidin protein from *S. avidinii*, placed under the control of an embryo specific promoter could possibly be used as a selection system for grape (see Perl *et al.*,

2003). The public availability of the assembled grapevine genome sequence in 2007–2008 will also make it easier for researchers to identify and use grapevine promoters that have specific spatial and temporal specificity. Grapevine microarray data and other HTP gene expression assays will also provide a wealth of information on key genes involved in specific processes and traits, providing the basis for transgenic experiments to confirm gene function.

3.4 Current Perceptions

The area of intellectual property (IP) rights covering plant transgenic technologies, genes, promoters, and new genotypes and phenotypes is complex. However, the CAMBIA organization (<http://www.cambia.org>) has made available a variety of free tools and information on patents and IP that greatly assist the public scientist in determining their “freedom to operate” status. The CAMBIA site also hosts free patent searching through the Patent Lens portal and grapevine specific patents can be found by using this resource. At the present time, patents involving grapevine are reasonably specific and not of a nature that will inhibit GM research.

The global grape and wine industry is a consumer-driven industry and any negative media attention can very quickly affect company sales and marketability of a product. Negative media reports in 1999 and concerns by both consumers and some winemakers resulted in the champagne producer Moët & Chandon quickly ending a field trial of GM vines. Because of public concern about GM plants, especially in the major European market, the industry in all parts of the world has taken a wait and see approach. In Australia, many in the industry are aware of the potential benefits of GM technology and while supporting the research have also publicly stated: “No genetically modified grapes or yeasts are used in the production of Australian wines. And there will be no commercial use of genetically modified organisms until it is clear they are safe, of high quality, and beneficial to consumers.” This industry stance has now been adopted in many other countries. As outlined above, and in Tables 1 and 2, research is actively continuing into genetic modification as a means of vine improvement. Genetic modification of yeast

is also a very active area of research for improving wine quality (Pretorius, 2000; Schuller and Casal, 2005) and some modified strains have recently been given “Generally Regarded As Safe” status by the Food and Drug Administration (FDA) in the United States and commercialized in both Moldova and the United States (Husnik *et al.*, 2006). It is expected that general acceptance of GM yeasts in commercial wine production by both the wine industry and consumers will help pave the way for similar acceptance of GM vines.

Olive

Eddo Rugini, Patricia Gutiérrez-Pesce and Rosario Muleo

Dipartimento di Produzione Vegetale, Università degli Studi della Tuscia, Viterbo, Italy

1. INTRODUCTION

1.1 History, Origin, and Distribution

Palynological, anthropological, and archeological evidences demonstrated the presence of some forms of olive during the last glaciation in the western and eastern Mediterranean regions 18 000 years BC (Carrion and Dupre, 1996; Watts *et al.*, 1996). Numerous studies confirmed that olives have been present for several thousands of years before its domestication in the Mediterranean basin, particularly in the Middle East. Olive was probably domesticated in the Jordan River valley ca. 5700–5500 BC (Zohary and Spiegel-Roy, 1975) and more precisely according to Liphshitz *et al.* (1991) domestication occurred during the bronze period (5200 BC). The spread of the cultivated olive to other countries of the Mediterranean region accompanied migrations of different civilizations (Egyptian, Phoenician, Greek, Etruscan, Roman, and Arab). Wild and domesticated olives grow in the same areas and show some morphological differences with cultivars, i.e., smaller fruit size and lower oil content in the mesocarp (Terral and Arnold-Simard, 1996). Two distinct wild olives have been recognized: *oleaster* and feral forms. *Oleaster* occupies primary niches in undisturbed areas as a constituent of evergreen plant associations. Wild and cultivated varieties, representing two genetically separated complexes, have been interconnected as a result of occasional hybridizations that could have allowed the introgression of genes from the wild forms

into the cultivated varieties. Due to their long life, there has been relatively little selection and the cultivated olives are assumed to be very similar to their progenitors (Liphshitz *et al.*, 1991).

1.2 Botanical Description

There are 30–40 *Olea* species distributed in Oceania, Asia, Africa, and the Mediterranean region (Johnson, 1957), which are included within the Oleideae subfamily, and in the Oleaceae tribe and are considered to be a diploid species ($2n = 2x = 46$). The 1C DNA content has been estimated for some cultivars to be approximately 2.2 pg (picogram) (Rugini *et al.*, 1996) corresponding to a genome size of 2200 Mb.

The genus is divided into two subgenera, *Olea* and *Paniculatae*; subgenus *Olea* is divided into section *Olea* (cultivated olive and wild relatives) and section *Ligustroides*. The section *Olea* includes the complex of *Olea europaea* L., the Mediterranean olive tree (Green and Wickens, 1989). These authors distinguished four subspecies according to their morphology and their geographical distribution: *O. europaea* ssp. *europaea*, of the Mediterranean basin; *O. europaea* ssp. *laperrinei* (Batt. and Trab.) Ciferri of the Sahara Massifs; *O. europaea* ssp. *cerasiformis* (Webb. and Berth.) Kunk. and Sund. of the Canary Islands and Madeira; *O. europaea* ssp. *cuspidata* (Wall. Ciferri) of Asia (China, India, Pakistan, Iran, South Arabia) and southeast Africa. *O. europaea* ssp. *europaea* includes the cultivated

varieties (var. *europaea*) and wild plants (var. *sylvestris* = Oleaster) of the Mediterranean basin. Green and Wickens (1989) and Zohary (1994) hypothesized that the different wild forms of the *O. europaea* complex have contributed to the evolution of cultivated olive.

The great diversity of germplasm in the Mediterranean region represents an important source for future breeding. To exploit this resource, more information is needed, including the level and distribution of variability within cultivars, the genetic relationships among cultivars and with wild olives, the markers linked to the main traits under selection, characterization of genes, their regulation and expression at different developmental phases in different tissues. Until few years ago, germplasm of *O. europaea* has been identified by morphological descriptions. Then, biochemical and molecular analysis have been developed by using isozymes and randomly amplified polymorphic DNA (RAPD) primarily for cultivar identification, study the taxonomy within the genus and the relationships between cultivated and wild olives, for determining the origin of cultivars, and to map and to identify the markers linked to the most important agronomic traits. Molecular biology allows the evaluation of the genetic variability in a precise manner across technologies that emphasize any genetic changes by means of biochemical analysis (isoenzymes and allozymes) or DNA marker analysis using restriction fragment length polymorphism (RFLP), RAPD, inter-simple sequence repeat (ISSR), amplified fragment length polymorphism (AFLP), simple sequence repeat (SSR), and single nucleotide polymorphism (SNP). Isozymes were first used for cultivar identification (Pontikis *et al.*, 1980) and subsequently cultivar identification has been based on DNA markers, i.e., RAPDs (Bogani *et al.*, 1994; Fabbri *et al.*, 1995; Cresti *et al.*, 1996; Wiesman *et al.*, 1998; Bartolini *et al.*, 2006a), using different protocols (Belaj *et al.*, 1999, 2001, 2002; Mekuria *et al.*, 1999; Barranco *et al.*, 2000; Gemas *et al.*, 2000; Besnard *et al.*, 2001b). More than 200 cultivars in the World Olive Germplasm Bank (Cordoba, Spain) have been characterized using relatively few primers. Cultivars with common and distant areas of origin show high similarity, which supports the hypothesis of a multilocal selection for most cultivars (Besnard *et al.*, 2001a). AFLP data are available on the cultivars of most of the Italian

regions (Baldoni *et al.*, 2000; Bracci *et al.*, 2006) and some cultivars from Tunisia (Grati Kamoun *et al.*, 2006). For cultivar characterization, SSRs (Rallo *et al.*, 2000; Sefc *et al.*, 2000; Carriero *et al.*, 2002; Cipriani *et al.*, 2002; Marra *et al.*, 2006; Reale *et al.*, 2006), ISSR (Pasqualone *et al.*, 2001; Vargas and Kadereit, 2001), and sequence-characterized amplified region (SCAR) markers have also been attempted from RAPDs (Hernandez *et al.*, 2001b).

The two different forms of wild olives (oleasters and feral forms) have been distinguished by isozymes (Lumaret *et al.*, 1997) and AFLP (Angiolillo *et al.*, 1999). RFLP markers have been identified from mitochondrial (mtDNA), chloroplast (cpDNA), and nuclear DNA, and together with isozyme markers, they provide evidence for the survival of indigenous oleaster populations, particularly in the western part of the Mediterranean region. The domesticated olive represents a subset of the genetic variation in genuinely wild olive populations that persist today (Lumaret and Ouazzani, 2001). The phylogenetic relationships within the *Olea* genus have been assessed by nucleotide variation at a noncoding cpDNA region in some *Olea* species and four groups could be distinguished: *Olea capensis* and *Olea lancea*, both belonging to subgenus *Ligustroides*, the *Olea* forms from southeast Africa, those from Asia, and the taxa of northwest Africa and the Mediterranean region, which include the cultivated olive (Baldoni *et al.*, 2002). These relationships are consistent with those previously reported with cpDNA-RFLPs (Lumaret *et al.*, 2000).

Five distinct chlorotypes were distinguished on the basis of cpDNA restriction patterns, and wild olives were more variable than cultivars (Amane *et al.*, 1999). With mtDNA-RFLPs, different mitotypes have been identified. Within wild populations, a clear distinction exists between the eastern and western Mediterranean regions. For cultivars, a more complex mitotype distribution exists, probably due to exchanges of plant material during the long history of olive cultivation (Besnard and Berville, 2000; Bronzini de Caraffa *et al.*, 2002a, b). The colonization history of *O. europaea* has been analyzed based on internal transcribed spacer 1 (ITS-1) sequences, RAPD, and ISSR markers in Macronesia (Hess *et al.*, 2000). *O. europaea* retroelements have also been identified (Hernandez *et al.*, 2001a) and the

total copy number in the genome has been estimated (Stergiou *et al.*, 2002). The cpDNA-RFLP, performed on 15 *Olea* taxa, has resulted in the clear separation of species in Section *Olea* from those of Section *Ligustroides*; the latter group of species appears to possess ancestral variants of cpDNA (Lumaret *et al.*, 2000). AFLP analysis has been used to distinguish *Olea* species from the Indian Ocean and Oceania from the species of East Africa and Asia, which clustered together. *Olea* spp. from northwest Africa, e.g., *O. laperrinei* and *O. maroccana*, showed a higher level of similarity with cultivated and wild samples of *O. europaea* (Angiolillo *et al.*, 1999). Analysis performed on ribosomal DNA (rDNA), cpDNA, and mtDNA polymorphisms has confirmed the ancient separation of the genus *Olea* into two subgenera: Asia-Australia (subgenus *Paniculatae*) and Africa (subgenus *Olea*). Three distinct main phyla were characterized: *O. cuspidata* – *O. chrysophylla* (= *cuspidata* phylum) of Asia, *O. africana* (= *africana* phylum) of East and South Africa, and *O. europaea* – *O. laperrinei* – *O. maroccana* – *O. cerasiformis* (= *europaea* phylum) of the Mediterranean region, Sahara, and northwest Africa (Besnard and Bervillé, 2002; Besnard *et al.*, 2002a, b). According to cpDNA and mtDNA analysis, *O. europaea* ssp. *maroccana* represents a well-differentiated and relict taxon, belonging to the same subtaxon as *O. europaea* ssp. *guanchica* (Medail *et al.*, 2001).

Two tandemly repeated sequences (81 bp and pOS218) were isolated by Katsiotis *et al.* (1998) and were localized by *in situ* hybridization on the chromosomes, showing a telomeric or interstitial location. These elements are also present in oleasters, *O. chrysophylla* and *O. africana*, but are absent in other genera of the Oleaceae, i.e., *Phyllirea*, *Forsythia*, *Ligustrum*, *Parasyringa*, and *Jasminum*. The amount and organization of heterochromatin and the frequency of other tandemly repeated sequences (*Oe*Taq80, *Oe*Taq178, *Oe*GEM86) indicate that DNA content is positively correlated with the copy number of DNA repeats in the genomes of different *Olea* forms (Bitonti *et al.*, 1999; Lorite *et al.*, 2001; Contento *et al.*, 2002). Cytological hybridization of these tandem repeats has made it possible to distinguish most of the olive chromosomes and to reveal structural heterozygosity in three chromosome pairs (Minelli *et al.*, 2000).

1.2.1 Use of molecular markers in genome analysis and improvement of olive

The first RAPD analysis was carried out on 11 cultivars by Bogani *et al.* (1994) by using five arbitrary primers. Only 17 primers produced reproducible polymorphic markers among all 40 primers used by Fabbri *et al.* (1995) that were able to distinguish 17 different cultivars, but no apparent relationship between olive cultivars and their geographic origin was shown. Many other researchers used RAPD to distinguish among both cultivars of *O. europaea* and diverse species of *Olea* (Roselli *et al.*, 1995, 2002; Cresti *et al.*, 1996; Vergari *et al.*, 1996; Perri *et al.*, 1997; Cavalieri *et al.*, 1998; Wiesman *et al.*, 1998). A high number of fragments per primer in RAPD analysis were found by Mekuria *et al.* (1999). The same authors found a high degree of genetic similarity among the cultivars Manzanillo, Kalamata, Nevadillo, Picual, Correggiolo, while for small genetic variations somatic mutations might have occurred. As far as the other analyzed cultivars were concerned, a high degree of heterogeneity was found and the authors suggested that misnaming has occurred on several occasions. Recently AFLP has been used for marker fingerprinting and has produced a sufficient number of polymorphic fragments to separate the different species of *Olea* and to group together the genotypes within the cultivar of *O. europaea* (Angiolillo *et al.*, 1999; Baldoni *et al.*, 2000). By this technique, genotypes from different geographical origin were grouped together using five AFLP primers, which produced about 290 polymorphic fragments. A combination of three RAPD primers was proposed for the identification of the cultivars (Besnard *et al.*, 2001b). Chloroplast genomes have been a primary source of molecular data for genetic variability analyses in *Olea* as they are maternally inherited. Despite the variability of nuclear markers, RFLPs of chloroplast DNA showed a low level of variation among cultivars (Amane *et al.*, 1999). The relatively rapidly evolving chloroplast spacers and introns are widely used in systematic studies at low taxonomical ranks in *Olea* (Baldoni *et al.*, 2002; Besnard *et al.*, 2002a, b). Besnard *et al.* (2000) used RFLPs to analyze mtDNA and cpDNA of a progeny derived from the cross of male sterile “Olivière” and “Arbequina”, and established that male sterility is maternally

inherited and is associated with the chlorotype CCK and mitotype MCK.

SSRs or microsatellites are of great interest as they are co-dominant, robust, and highly informative and reproducible. The advantages of SSRs compared with other molecular markers in the olive have been demonstrated by Belaj *et al.* (2003). Many SSRs have been isolated in the olive, (Rallo *et al.*, 2000; Sefc *et al.*, 2000; Carriero *et al.*, 2002; Cipriani *et al.*, 2002; De La Rosa *et al.*, 2003) a large number of genotypes have been used by these authors and others for genotyping olive germplasm resources (Belaj *et al.*, 2004; Lopes *et al.*, 2004; La Mantia *et al.*, 2005; Montemurro *et al.*, 2005; Chessa *et al.*, 2006; Diaz *et al.*, 2006). Intravarietal allelic differences at SSR loci have been identified (Cipriani *et al.*, 2002; Lopes *et al.*, 2004; La Mantia *et al.*, 2005) that could be explained as somatic mutations, occurring in long-living trees that reproduce by vegetative means (Cipriani *et al.*, 2002; La Mantia *et al.*, 2005).

The SNPs represent the next generation of markers in plants because by using this technique it is expected to obtain a better understanding of the genetic basis for complex characters in plants including production, development, strategies of adaptation to abiotic and biotic stresses, and to realize the potential of genetic improvement programs. Genes of known sequence that putatively influence the traits of interest can be selected and mapped, and functional maps can be constructed (Schneider *et al.*, 2002). A new SNPs technology was reported (Muleo *et al.*, 2006), high-resolution DNA melting analysis (HRMA), for either mutation scanning of polymerase chain reaction (PCR) products or genotyping with unlabelled probes, which have a very high sensitivity for scanning procedures, for detecting substitution and indel mutations, and for detecting heterozygous SNPs within a large PCR product.

1.2.2 Genome map

Normally, for observing the characters expressed at the mature phase such as, fruit characteristics, oil content and quality, tree architecture and size, it is necessary to attend 15–18 years of the life of a olive tree; however, it is possible to force seedling growth in order to obtain early flowering and first production at 3–4 years after germination (Santos Antunes *et al.*, 1999). Nonetheless, for

certain traits it would be more efficient to select the plants at the seedling stage, if molecular markers linked to these traits were available. Those markers co-segregating with the trait of interest are the tools for marker-assisted selection (MAS). The first attempts to construct a linkage genome map for olive have been reported (Baldoni *et al.*, 1999; De la Rosa *et al.*, 2003) using the progeny derived from the cross between Leccino and Dolce Agogia. The use of an F₁ progeny, allowing the use of markers in the condition of pseudo-testcross, limits the number of useful markers and results in the construction of two distinct maps; one for each parental line. This can be overcome by the use of markers that produce a very high number of scorable markers in each reaction, i.e., AFLPs and by the use of co-dominant markers, i.e., microsatellites, to anchor the different maps in a general one for the species. In the “Leccino” map, 249 markers (110 RAPDs, 127 AFLPs, 8 RFLPs, and 3 SSRs) were linked. This resulted in 22 major linkage groups and 17 minor groups with less than 4 markers. In the “Dolce Agogia” map, 236 markers (93 RAPDs, 133 AFLPs, 6 RFLPs, and 4 SSRs) were linked. In this case, 27 major linkage groups and 3 minor groups were obtained.

Another integrated molecular linkage map was constructed, based on RAPD, SCAR, and SSR markers, on a population of 104 individuals generated from F₁ full-sib family of a cross between “Frantoio” and “Kalamata” (Wu *et al.*, 2004). Twenty-three linkage groups were mapped for “Kalamata”, covering 759 cM of the genome with 89 loci and an average distance between loci of 11.5 cM. Twenty-seven linkage groups were mapped for “Frantoio”, covering 798 cM of the genome with 92 loci and an average distance between loci of 12.3 cM. For the integrated map, 15 linkage groups covered 879 cM of the genome with 101 loci and an average distance between loci of 10.2 cM. The size of the genomic DNA was estimated to be around 3000 cM. The maps are the starting point for studies on the structure, evolution, and function of the olive genome.

1.2.3 Gene cloning

Genes, codifying proteins involved in essential biochemical processes, were isolated in olive. The first one was the stearyl-acyl carrier protein desaturase (Baldoni *et al.*, 1996), the enzyme key

Table 1 Number of sequences in olive deposited in the GeneBank up to September 30, 2006

Nuclear sequences	109
Ribosomal	90
cpDNA + mtDNA	136
EST	26
sequence-related amplified polymorphism (SRAP) markers	44
Retrotransposon	16

in the trial of the fatty acids insaturation of the membranes and of the accumulation lipids. It determines the formation of the double connection that transforms the stearic acid into oleic acid, the main constituent of olive oil. Different genes codifying for a family of proteins that induce allergic symptoms in humans were also isolated. These proteins differed among themselves in length but all of them are expressed during the formation of the pollen (Lambardero *et al.*, 1994; Villalba *et al.*, 1994; Asturias *et al.*, 1997; Batanero *et al.*, 1997; Ledesma *et al.*, 1998).

There are 109 nuclear gene sequences deposited in the GenBank up to September 30, 2006. Most of them are the sequences of the cytoplasmatic genome, while the number of expressed sequence tags (ESTs) is reduced (Table 1). Many genes encoding key enzymes for fatty acid biosynthesis and modification, triacylglycerol synthesis and storage have been isolated. These are enoyl-acyl carrier protein reductase (*ear*), stearyl-ACP desaturase, $\omega 6$ plastidial desaturase (*fad6*), $\omega 3$ plastidial desaturase (*fad7*), cytochrome b5 (*cyt b5*), $\omega 6$ cytoplasmic desaturase (*fad2*), $\omega 3$ cytoplasmic desaturase (*fad3*), acyl Co-A diacylglycerol acyltransferase (DGAT), and oleosin (Giannoulia *et al.*, 2007). Stearyl-ACP desaturase (Baldoni *et al.*, 1996) is the key enzyme for the conversion of saturated stearic acid (C18:0) to mono-unsaturated oleic acid (C18:1), the main component of olive oil and responsible for its high dietary value. A complementary DNA (cDNA) has been isolated encoding a fatty acid desaturase, which is responsible for biosynthesis of a trienoic acid, linolenic acid, a major component of chloroplast membranes and a precursor of the oxylipins, i.e., methyl jasmonate. The latter is important in signal transduction pathways relating to plant development and responses to stress, and have been studied in leaves, anthers, and embryos (Poghosyan *et al.*, 1999). Two cytochrome

b₅ genes and their spatial and temporal patterns of expression have been characterized during floral and fruit development (Martsinkovskaya *et al.*, 1999). The expression of oleosin gene is strongly embryonic-stage dependent and the transcript reaches maximum levels at midtorpedo stage and thereafter declines, coinciding the stages of most oil accumulation in embryo tissues, while in mesocarp tissues oleosin gene is not expressed (Giannoulia *et al.*, 2007). A triterpene synthase cDNA, cloned from olive leaves by PCR amplification using primers designed from oxidosqualene cyclases, codes for the lupeol synthase protein (Shibuya *et al.*, 1999). The differential expression of DGAT genes has been evaluated in different olive tissues (Giannoulia *et al.*, 2000). The sequence of a partial cDNA clone (1402 bp) of the chloroplast ribulose 1,5-bisphosphate carboxylase large subunit (*rbcL*) gene of olive has been compared with that of other genera in order to establish the systematic position of the Oleaceae family (Wallander and Albert, 2000). Similarly, the chloroplast *ndhF* gene has been sequenced for phylogenetic studies (Olmstead *et al.*, 2000).

1.3 Economic Importance

Olive is one of the most important tree crop species of the Mediterranean area and its global importance is rapidly increasing. The traditional area of olive cultivation is the Mediterranean basin, which accounts for 95% of the olive groves of the world. Spain, Italy, and Greece produce almost 99% of the world's olive oil and more than 80% of table olives (IOOC, 2005). In 2005, world cultivation was approximately 7.5 million ha, on 60% of which represents the main crop, with a production of approximately 14 442 metric tons destined to both oil and fresh consumption (FAOSTAT, 2006). The world production and consumption trend of olive oil in the last 30 years have increased significantly and will continue to increase considering the recent introduction of its cultivation in Japan, Australia, China, South America, and South Africa. It has been estimated that in the year 2008 olive production will rise by about 3 million tons, as a result of an increase of olive cultivation of 120 000 ha per year.

The traditional Mediterranean diet has demonstrated to be the most beneficial for maintaining good health due to the high quantity of

antioxidants present in olive oil, fruit, and vegetables. Among the antioxidants, α -tocopherol is the main tocopherol found in olive with concentrations varying from 98 to 370 mg kg⁻¹ depending on the olive cultivar and the environmental conditions (Psomiadou *et al.*, 2000; Rotondi *et al.*, 2004). Furthermore, olive has a characteristic-free acid content and composition as well as total polyphenol concentration that makes olive oil one of the healthiest vegetable oils, and efforts to improve other oil-producing crops have attempted to imitate its composition (Cahoon and Shanklin, 2000; Bruner *et al.*, 2001; Rahman *et al.*, 2001). Oil accumulation occurs in olive fruit mesocarp and to a lesser extent in the olive seed (Harwood and Sanchez, 2000). The low percentage of oil (which rarely exceeds 25% of fresh weight), the peculiar composition of oleic acid (a C18:1 mono-unsaturated fatty acid), which is almost 75% of the total triacylglycerides while linoleic acid is only 10%; however, the fatty acid composition could change according to variety and environmental conditions, and the parameters of quality in native olive oils make the genetics of oil metabolism of special interest for the clarification of gene regulation involved in oil accumulation.

Although the production of oil and table olives is by far the most important reason for olive cultivation, the species serves other important functions. In several countries of the Mediterranean basin the olive has been closely associated from ancient times with the traditional landscape, and its presence, together with cypress, is typical of religious sites. In these areas, it is one of the few species with characteristics of high drought resistance, and it is suitable for use in calcareous, rocky, and sloping soils. Finally, its wood is of great value due to its natural durability and beauty for furniture and parquet; hence, in some areas of south of Italy, it represents a secondary source of profit from olive groves.

1.4 Traditional Breeding: Objectives; Tools and Strategies; Achievements and Limitations

More than 1000 cultivars under cultivation originated mostly from selections made by growers over many centuries, and often they have not been replaced by new genotypes suitable for intensive

cultivation. Plants for intensive cultivation should be of reduced size, reduced apical dominance, and constant and high productivity in terms of fruit and oil. Selection of constant self-fertile genotypes having fruit with a suitable composition of fatty acids with high polyphenol content and with a correct pattern of fruit ripening in terms of intensity of the degradation of phenolic and pectic compounds and tolerance to frost, salts, drought, diseases, and pests should be attempted. No cultivated species contain desirable traits such as, biotic stress resistance, adaptation to extreme environmental conditions, different plant vigor, and canopy architecture that could be introgressed into cultivars by conventional breeding or by gene transfer. Those plants are conserved distant from the center of origin.

Breeding in olive is difficult to carry out due to the very long juvenile period (>10 years) and different flower fertility: full male sterility (Tombesi, 1978; Fontanazza, 1993; Bartolini and Guerriero, 1995), self-fertility (Fontanazza *et al.*, 1990), and partial self-fertility. In the last two cases, flower emasculation is necessary; however considering the much reduced size of the flower and the low percentage of setting (1–2%) this operation is tedious and time consuming. Some genes controlling flower initiation in *Arabidopsis* have been identified (Yanotsky, 1995; Simpson *et al.*, 1999). Two of them, *LEAFY* (*LFY*) and *APETALA1* (*API*), have been used to transform *Citrus* (Pena *et al.*, 2001) and results showed flower initiation in 1-year-old plantlets.

At present, the juvenile period can be shortened by an accurate method of plant training by continuous illumination, although the length of juvenility is genotype dependent. In addition, the choice of right cultivars as pollinators, such as Leccino and Verdale, can reduce the juvenile period of offspring, and also cv. Leccino when used as mother plant, contrary to the progeny of cv. Coratina, Picholine, and Tanche (Bellini, 1990; Fontanazza and Bartolozzi, 1998). Up to now, only a few cultivars have been obtained by breeding programs, producing interesting plants at F₂ generation. Two cultivars, one for table and one for oil extraction; the last one being also resistant to peacock spot, have been selected. It seems that some characters as vigor, leaf size, fruit shape are dominant in F₁ progenies (Rugini and Lavee, 1992; Bellini *et al.*, 1995). Other characters

such as carpological traits of fruit, blossoming intensity, fruit set, period of fruit ripening and yield have been considered (Bellini, 1993; Parlati *et al.*, 1994; Bellini *et al.*, 1995). Recently, the embryo rescue technique has been applied with successful results in hybrid plants between the cultivars Mary and an Iranian local variety because many plants were obtained that grew normally in pots (Hossein Ava and Hajnajari, 2006). In Spain, agronomic characterization of selections from crossings between the main Spanish cultivars by using different methodologies for the reduction of the juvenile period of seedlings revealed interesting characteristics of the offspring regarding oil content and yield efficiency (Leon *et al.*, 2006). In Italy, field evaluation of selections derived from a breeding program between several local varieties showed a different vegetative and productive behavior among the genotypes (Bartolini *et al.*, 2006b; Pannelli *et al.*, 2006; Ripa *et al.*, 2006).

Other attempts of genetic improvement, such as clonal selection and mutation through γ -irradiation, did not give good results. Protoplast technology, haploid culture, somaclonal variation, changes in ploidy level, and somatic hybridation have also been tried with rare success due to the absence of efficient methods of regeneration from *in vitro* grown tissues.

The selection of new clones has not been completely explored, so it is important to search new accessions to solve the present lack of suitable cultivars (Morettini, 1972; Berenguer, 1978; Fontanazza, 1987). More recently, clonal rootstocks have been selected with high rooting ability and ability to control scion vigor (Baldoni and Fontanazza, 1990) and many accessions, particularly for small tree size are under observation (Pannelli *et al.*, 1993). The criteria for the selection of rootstocks include good rooting potential, control of scion vigor, resistance to drought, saline and heavy soils, resistance to root diseases, and graft compatibility with the scion. Very few studies have addressed the selection of clonal rootstocks. Preliminary work was concerned with the influence of rootstocks on scion performance. Some rootstocks are able to control scion vigor and confer cold tolerance (Pannelli *et al.*, 2002).

Stable mutation rarely occurs in olive, while chimeric plants of cv. Frantoio (Roselli, 1982) and

Canino (Parlati *et al.*, 1994) have been observed. On the contrary dwarf plants from artificially irradiated rooted cuttings of cv. Ascolana Tenera have been obtained by Roselli and Donini (1982) and they are used as ornamentals. Other compact mixoploid mutants have been obtained following irradiation of “Frantoio” and “Leccino” plantlets resulting in the selection of dwarf “Leccino”, which is self-sterile and late blooming and seems to be a promising rootstock (Pannelli *et al.*, 1990). The mixoploid mutants allowed us to select triploid and tetraploids plants (Rugini *et al.*, 1996).

1.4.1 Protoplast technology

Protoplast fusion is useful to produce hybrids from cross-incompatible varieties and species. Furthermore, protoplasts allow genetic modifications by introducing exogenous DNA by liposome or cellular organelles. Viable protoplasts from hypocotyls, cotyledons, and leaves of micropropagated shoots were isolated and cultured, and in some cases microcalli have been achieved (Rugini, 1986; Cañas *et al.*, 1987; Mencuccini, 1991; Perri *et al.*, 1994a). This technology cannot be applied at this moment in olive because regeneration is not possible yet from derived protoplast callus. Although protoplast technology may be useful in genetic improvement research in olive, one should not expect good results, since somaclonal variation and chromosome rearrangement could heavily change the expected results substantially.

1.4.2 Haploids and homozygotic plants

Considering the self-sterility characteristic of olive plants and the long juvenile phase, the achievement of homozygous plants by self-fertilization seems very improbable. Homozygous plants would be of great interest for isolation of mutants and recessive traits. Anthers and ovary or pollen and ovule cultures should be explored with the aim to produce dihaploid plants by doubling the chromosome number. Many efforts have been paid in the past to recover haploids of olive but with little success (Mulè *et al.*, 1992; Perri *et al.*, 1994b). Recently, promising results were obtained employing a new method of isolated microspore culture, which led to cell division and pro-embryos

formation in the cultivar Arbequina (Bueno *et al.*, 2006).

1.4.3 Somaclonal variation

For increasing the induction of genetic variation, the selection of spontaneous mutants that could occur during the regeneration phase, a common and efficient technique consists in the co-cultivation of callus, tissues, or organs in a medium containing a selective agent in order to create a selective pressure conditions that induce changes or allow the selection of already changing cells. The selective agent can be of biotic or abiotic origin such as, ionizing radiation, fungal filtrate, purified toxin of some pathogens, high osmotic pressure, etc. Reports on somaclonal variation in olive have not been reported yet following plant production through the three methods of plant production. Some phenotypic variations of *in vitro* grown shoots or whole plants have been observed but they were only of temporary effect of juvenility induced by the *in vitro* culture. Today, this technique can be exploited by using the potent cyclic somatic embryogenesis of some cultivars as Canino.

1.4.4 Changes in ploidy level

Rugini *et al.* (1996) described the procedure by which triploid and tetraploid plants of the cultivar Leccino have been produced. Mixoploid plants, obtained by γ -irradiation of cuttings, produced some bigger fruits than others, which resulted in triploid seedlings. Tetraploids plants were obtained by *in vitro* culture of axillary bud stimulation of those mixoploid plants. During *in vitro* culture the mixoploid shoots split spontaneously in two kinds of shoots; they were recognizable by a wider, longer, and thicker leaves than diploid ones. Isolation of stable tetraploids by organogenesis has so far been unsuccessful. In field trial $4n$ plants were smaller than $2n$ plants. These plants are characterized by more flexible branches and the absence of a juvenile phase and by having larger leaves and fruits than plants with normal ploidy level while the intensity of blossom were scarce (Figure 1). When tested as rootstocks, they seemed to reduce the growth of the scions (Figure 2).

Figure 1 Phenotypic characteristics of branches, leaves, and fruits of diploid and tetraploid plants of cultivar Leccino

2. DEVELOPMENT OF TRANSGENIC OLIVES

Very few reports have been presented on biotechnological approaches of improving olive trees. Genetic improvement in olive has targeted to change some traits including self-fertility, oil content and composition, parthenocarpy, abiotic stress tolerance, plant habit, fruit ripening, regular cropping, and resistance to pathogens and pests; however, the low efficiency of both conventional and modern techniques for genetic improvement suggests that genetic transformation by alien gene transfer could be a promising technique to speed up the development of new cultivars. Several genes of different origins that govern these characters have been identified; however, development of efficient regeneration methods from mature tissue of elite selections remains the limiting factor for using this technology. In olive, two procedures have been used to accomplish gene transfer into plant cells: *Agrobacterium*-mediated gene transfer and microprojectiles coated with DNA.

Most of the reports on transformation and isolation of transgenic plants of olive have involved *Agrobacterium tumefaciens* or *Agrobacterium rhizogenes*. These bacteria transfer a segment of the transfer DNA (T-DNA) known as Ti or ri plasmid into the nuclear genome of the plants (Chilton *et al.*, 1982). The efficiency of transformation depends on several factors such as, bacterial strains, plant cell competence, transgenic

Figure 2 Tetraploid plant (a) and diploid plants (b) of cultivar Leccino used as rootstocks in the experimental field at the Università della Tuscia, Viterbo

cell selection, and plant regeneration methods. In olive, the best strain of *A. rhizogenes* resulted is 1855 (E. Rugini, personal communication).

Biolistic has emerged recently as a simple and efficient technique for stable genetic transformation of recalcitrant species, and for studying gene expression and regulation. Most recently, transient expression in various tissues of woody species have been achieved by using microprojectile-mediated DNA delivery (Ellis *et al.*, 1991; Goldfarb *et al.*, 1991; Charest *et al.*, 1993; Duchesne *et al.*, 1993; Hay *et al.*, 1994); however, genetic transformation requires the optimization of several factors, including the *in vitro* regeneration systems, the methodologies for DNA delivery, and a high expression of the introduced gene in the plant tissue. The only DNA delivery system being used in olive up till now is DNA delivery by microprojectile bombardment (Lambardi *et al.*, 1999).

In olive, genetic transformation experiments have been realized aiming at the induction of

modified growth habit and/or disease resistance (Rugini *et al.*, 2000).

2.1 Explants Used

The recovery of transgenic plants depends on the number of transformed cells and the possibility to differentiate into shoots or embryos. The most common explants experienced in olive for transformation were leaf discs, leaf petioles, zygotic and somatic embryos, and whole shoots to induce rooting by *A. rhizogenes*. Immature zygotic embryos, capable of inducing somatic embryogenesis, were also used with some success (Rugini and Fedeli, 1990; Mencuccini *et al.*, 1997). Attempts to produce transgenic whole plants from leaf discs or petioles of cultivars Moraiolo and Dolce Agogia with the aim that the transgenic cells for *rol* genes, which are involved in hormone sensitivity, could lead to regeneration, was unsuccessful but only transgenic callus

was recovered (Mencuccini, 1994; Mencuccini *et al.*, 1999). At present, the best explants used for transformation, which allowed recovery of transgenic plants by using *Agrobacterium*, are somatic embryos of the cv. Canino, which are able to produce continuous cycles of cycling embryogenesis from epidermal cells (Rugini *et al.*, 1999).

2.2 Selective Marker

The *neomycin phosphotransferase II* (*nptII*) gene, encoding resistance to the antibiotic kanamycin, is very commonly used in transformation experiments. This gene inactivates other aminoglycoside antibiotics such as paromomycin, neomycin, and geneticin (Yoshikura, 1989). Efficient selection of the transformed cells is usually carried out with the selective antibiotic kanamycin at a concentration 50–100 mg l⁻¹ according to the explant. The critical concentration of kanamycin and the time of application of the selective pressure must be previously determined for each type of explant. The *in vitro*-grown apical olive shoots stop growing even at 30–40 mg l⁻¹ of kanamycin; while 20–25 mg l⁻¹ kanamycin in liquid medium is sufficient to inhibit the greening of single white embryos, grown in the dark, after exposure to light. The selection of transformed embryos, based on visual observations, attached to morphogenic masses (in the solid medium) take a long time even with high concentration of kanamycin, greater than 100 mg l⁻¹, probably due to the scarce mobility in the tissue. Considering this fact, selection of transgenic embryos should be carried out on embryos or embryogenic masses using a shaken liquid medium, initially for 2 days in the dark to avoid kanamycin degradation, then in the light (Rugini *et al.*, 2000).

2.3 Strategies for Regenerating Whole Plants

At present, besides zygotic explant, regeneration of shoots or embryos from mature explants of cultivars can be carried out only by using *in vitro*-grown shoots, thus an efficient method of micropropagation is essential.

2.3.1 Axillary bud stimulation

The first efficient protocols for *in vitro* propagation of the olive cultivars by axillary bud stimulation were reported by Rugini (1984) who formulated a medium specifically for this specie (Olive Medium or OM, or Rugini Olive Medium from DUCHEFA). The medium was formulated by analyzing the mineral element contained in the mature seeds. This medium is currently used for propagation of more than 50 olive cultivars in commercial plant production in Italy (Zuccherelli and Zuccherelli, 2000).

The axillary bud stimulation allows the rapid growth, better performance, and higher qualitative characteristics of the *in vitro*-grown plants than plants derived from propagation by stem cutting. Furthermore, *in vitro* propagation permits a high percentage of rooting of the explants even in those cultivars considered recalcitrant to propagation by cutting (Briccoli Bati and Lombardo, 1995). Exogenous treatment with putrescine is normally essential for rooting induction and for improving root system quality and plant growth (Rugini and Wang, 1986; Rugini, 1992; Rugini *et al.*, 1997). The marked effect of putrescine on rooting is presumably due to a general low content of endogenous polyamines in olive shoots at the end of proliferation, in comparison with other woody species (e.g., walnut and chestnut), which are not affected by putrescine treatment (Rugini, 1992; Rugini *et al.*, 1993). It was proved that putrescine affects early root differentiation similar to exogenous treatments with H₂O₂, a product of polyamine catabolism. These observations led to the hypothesis that putrescine acts during the root induction phase by means of an increase in peroxidase activity through H₂O₂. In fact, a drastic reduction of polyamines was observed at the basal part of able-to-root microcuttings, within 48 h after shoot preparation, even when they were cultured in putrescine-containing medium (Rugini *et al.*, 1997).

In the experimental field, the micropropagated plants behave in the same manner as plants derived from traditional propagation by cutting if the initial explants are collected from mature twigs (Figure 2). On the contrary, if initial explants come from suckers, the plants start blossom 2–3 years later. Neither phenotypic variations nor genotypic alterations of *in vitro* propagated plants till now

were observed by PCR-RAPD analysis (Rugini *et al.*, 1996; Briccoli Bati *et al.*, 2000; Garcia-Fèrriz *et al.*, 2000; Leva *et al.*, 2000).

2.3.2 Shoot organogenesis

Regeneration by organogenesis system should be very suitable because it occurs from single cell avoiding thus the chimerism in whole plant; however, the frequency is low in both zygotic and particularly in mature tissues of the cultivars. Adventitious shoots and roots were obtained for the first time from seedling explants by Gilad and Lavee (1974). Subsequently, Wang *et al.* (1979) described two histologically different meristematic tissues originating from olive callus, namely, cellular masses and nodules, which evolved, respectively, into adventitious roots and buds. Direct shoot regeneration was induced on section of hypocotyls of seed (Bao *et al.*, 1980), on cotyledons of mature seeds (Rugini, 1986), on calli derived from cotyledon segments proximal to the embryo axes of the cultivars, Tanche and Picual. These results suggested that a gradient of regeneration potential existed from the proximal to the distal region of olive cotyledons (Cañas and Benbadis, 1988).

Mencuccini and Rugini (1993) obtained adventitious buds in petioles from *in vitro*-grown shoots of cultivars Moraiolo, Dolce Agogia, and Chalkidikis but the efficiency of shoot organogenesis does not exceed 40% and it is heavily dependent on the cultivar, the position of petiole along the shoot (apical nodes better than basal ones), the medium/hormone combination, type of tissue, and the maintenance of darkness during culture. Regeneration has never been obtained from leaf discs and midribs, neither from petioles excised from field or potted plants. The regenerated plantlets did not show any morphological differences compared with the micropropagated donor plantlets.

2.3.3 Somatic embryogenesis

The first reports on somatic embryogenesis both from immature zygotic embryos and from mature tissues of various cultivars were by Rugini (1988) and Rugini and Caricato (1995), respectively.

Somatic embryogenesis occurred from zygotic embryos in high percentage in cv. Dolce Agogia, Leccino, Frantoio, and Moraiolo when the fruits were harvested at around 75 days after full bloom, while before or after this period a drastic reduction of frequency with high callus production was observed. The high embryogenic capacity could be maintained for at least 2 months, by storing at 14–15 °C the two and a half-month-old fruits, in which the small embryos continued to develop without losing their embryogenic capacity (Rugini, 1995). These results were confirmed by Leva *et al.* (1995) in cvs. Picholine, Frangivento, and Frantoio, while Pritsa, and Voyiatzis (1999) reported somatic embryogenesis also from 126-day-old zygotic embryos of the cv. Chalkidikis. Orinos and Mitrakos (1991) observed the highest embryogenic capacity in calli derived from radicle explants of mature zygotic embryos of wild olive (*O. europaea* var. *sylvestris*) after 21 days of culture on inductive medium with high concentration of auxin. Dissimilar morphogenetic expression of calli from different parts of mature embryo was observed also by Mitrakos *et al.* (1992) in the cv. Koroneiki, in Moroccan genotypes (Abousalim *et al.*, 2006), and cv. S. Agostino (Rugini and Tarini, 1986) and Nabali (Shibli *et al.*, 2001).

Rugini and Caricato (1995) developed a novel strategy named as “double regeneration system” that allowed somatic embryogenesis in two cultivars Canino and Moraiolo. It consists of regenerating first the adventitious buds from leaf petioles of *in vitro*-grown shoots and then subculturing their small leaflets, with the aid of a microscope, in a proper medium, until pro-embryo masses appear. Numerous somatic embryos easily develop with the ability to produce cyclic somatic embryogenesis from the epidermis or from subepidermal layer. The cyclic somatic embryogenesis (represented by normal and abnormal embryos) can be maintained indefinitely even in hormone-free medium, and some can also germinate (Figure 3) (Rugini and Caricato, 1995; Lambardi *et al.*, 1999; Benelli *et al.*, 2000; Rugini *et al.*, 2005). The conversion of normal embryos into plants is difficult; however, they in the field show juvenility with a retardation of blossom 3–4 years later than micropropagated plants by axillary bud stimulation. The continuous production of embryos from epidermal cells could

Figure 3 Cyclic somatic embryogenesis of cultivar Canino

be a great advantage in regenerating plants from transgenic cells avoiding callus formation, which could be a wide source of undesirable genetic variability. Somatic embryo germination can be achieved after their isolation into shaken liquid medium containing zeatin (Rugini and Caricato, 1995).

2.4 Alien Gene Transfer

Both an efficient *in vitro* regeneration method and the availability of suitable genes are essential factors. Up to now most of the transformation experiments have been carried out by using somatic embryos of cultivars because an efficient protocol for regeneration via cyclic somatic embryogenesis is available (Table 2).

2.4.1 Chimeric plants for increasing rooting ability

The rooting efficiency of *in vitro* grown shoots was increased by inoculating in the middle or in the basal part of the stem of the *in vitro* grown shoots with a scalpel infected with *A. rhizogenes* (Rugini, 1986, 1992). Roots that emerged from both the inoculation point and the basal part of shoots rarely resulted transformation with the *rol* genes (Rugini and Fedeli, 1990; Rugini, 1992; Rugini and Mariotti, 1992). Putrescine added to the hormone-free medium promoted early rooting and then the root system originated from shoots treated with *A. rhizogenes*, when transformed, produced numerous secondary roots during the first months on hormone-free medium. There were no results from the modification of the aerial parts in the field grown plants; however, according to our experience on plum trees, a drastic reduction of growth of the whole plant has been observed. Similar results have been obtained in cherry when it was grafted on a transgenic rootstock for *ri*-T-DNA (Biasi *et al.*, 2003; Gutiérrez-Pesce *et al.*, 2005).

2.4.2 Modifications of vegetative habits

Dwarf and semi-dwarf new varieties with changes in the canopy architecture regarding short and numerous shoots are more suitable for high-density olive groves. For other species, the use of the *rol* genes for plant improvement have demonstrated production of drastic effects on the plant architecture (Rugini *et al.*, 1991; van der Salm *et al.*, 1997, 1998; Perez-Molphe-Balch and Ochoa-Alejo 1998; Mercuri *et al.*, 2001; Zhu *et al.*, 2001), but scarce is the knowledge on the interaction of these genes with the genome of the

Table 2 Genetic transformation in olive cultivars

plant. Moreover, the development of plants with an extensive root system and/or with reduced water consumption could be an advantage in areas with scarce water availability. The *rolABC* genes of *A. rhizogenes* and the marker gene *nptII* were transferred to somatic embryos of the cultivar Canino by using the *A. tumefaciens* strain LBA4404 (Rugini and Caricato, 1995; Rugini *et al.*, 1999). Transgenic somatic embryos selected in liquid medium under light conditions converted into plantlets, which were transferred to the experimental field.

2.4.3 Increasing resistance to biotic and abiotic stress

The challenge of using biotechnological techniques is to generate broad resistance mechanisms, which are difficult to achieve by classical plant breeding approaches. *Osmotin* is a gene present in plants and belongs to the family related to proteins for pathogenesis, which are expressed under stress conditions, including pathogenic attacks. The tobacco *osmotin* gene has been employed for plant transformation since it is involved in the strategies developed by plants to resist to biotic and abiotic stresses. In fact, the role of *osmotin* as a defense protein in fungal disease is already known in grape (Salzman *et al.*, 1998) and potato (Liu *et al.*, 1994; Zhu *et al.*, 1995), although its accumulation has been proved to be induced also by abiotic stress conditions, such as osmotic or cold stresses (Zhu *et al.*, 1993; Grillo *et al.*, 1995). *Osmotin* gene is normally unexpressed in plant tissues, but 4 days of exposure to *Phytophthora infestans* induces the accumulation of both messenger RNA (mRNA) and protein (Zhu *et al.*, 1995). A longer exposure seems to be necessary to induce the response when low temperature or osmotic stress (NaCl) is used as elicitors. In fact, 7 days are necessary to reach a full response, i.e., an osmotin accumulation of 12% of the total cellular protein content (Grillo *et al.*, 1995). Moreover, in transgenic potato and tobacco plants osmotin overexpression is able to delay the development of *Phytophthora* disease symptoms (Liu *et al.*, 1994). However, its mRNA induction did not always lead to protein accumulation (Grillo *et al.*, 1995), suggesting transcription and post-translation controls.

In olive, transgenic plants for the *osmotin* gene under cauliflower mosaic virus (CaMV)

35S promoter, have been recovered from somatic embryos derived from petioles of cultivar Canino (Rugini *et al.*, 1999). The resistant clones were grafted on nontransgenic rootstock to speed up growth in order to evaluate their level of resistance to *Spilotea oleagina* (D'Angeli *et al.*, 2001). Other experiments are in progress with three genes from tobacco (*osmotin* + *chitinase* + *PRI*) in one construct with the CaMV 35S promoter. Transformed somatic embryos have been selected and plants have been established in the greenhouse (Rugini *et al.*, 2000).

Against olive fly (*Bactrocera oleae*), a group of researchers have developed a Minos-based transposon vector carrying a self-activating cassette that overexpresses the enhanced green fluorescent protein (EGFP). The self-activating gene construct combined with transposase mRNA present a system with potential for transgenesis in very diverse species (Koukidou *et al.*, 2006).

2.5 Evaluation of Transgenic Tissues and Plants

Transgenic plants for *rolABC* and *osmotin* produced in our laboratories were planted in the experimental field of the University of Tuscia, Viterbo, in 1999 under the authorization of the Environmental Minister for further evaluations.

2.5.1 Transgenic plants for *rolABC* genes

Reverse transcriptase PCR (RT-PCR) analysis of the putative transgenic clones confirmed the stable integration of the *rol* genes in the genome of the plants and their correct transcription.

Canino plants transgenic with the *rol* genes showed different expression of each gene in the organs studied although they are under the same promoter. The alien genes had influence on plant architecture; leaves had a wider angle of insertion on the stem and they showed changes in leaf blade shape with an increase number of internodes per stem due to the reduced internodes length. Furthermore, leaves of plantlets of transgenic clone-5 are enriched in chlorophyll content (Table 3). The transgenic clones showed different plant development and growth as demonstrated by the significant increase of the number of

Table 3 Some characteristics between transgenic plants of Canino for *rolABC* and the wild type

	Canino <i>rolABC</i>	Canino wild type
Chlorophyll A (mg g ⁻¹ fw)	18.42 ± 1.2	11.69 ± 1.2
Chlorophyll B (mg g ⁻¹ fw)	8.05 ± 1.5	4.14 ± 0.4
Total chlorophyll (mg g ⁻¹ fw)	26.47 ± 3.5	15.82 ± 1.6
Leaf area (mm)	36.3 ± 7.1	57.7 ± 12.2
LAM	17.7 ± 1.6	20.8 ± 2.1
LAMin	3 ± 0.4	4.3 ± 0.4
Number of internodes	10.6 ± 2.5	7.8 ± 1.1
Number of lateral shoots	6 ± 1.22	0.2 ± 1.4

internodes, wider angle of insertion of the leaves with a reduced area and less apical dominance as demonstrated by the outgrowth of lateral shoots giving them their bushy structure (Figure 4). Molecular analysis showed an overexpression of glycosyl-transferase elongation factor, *psbB*, *psbC*, and *psbD* genes in the transgenic clones compared to control plants (Figure 5). RT-PCR analysis showed different expression of *rol* genes in leaves

**Figure 4** Reduced size and bushy aspect of 8-year-old transgenic plants for *rolABC* and control of cultivar Canino

and stem from the *in vitro* grown clone-5, and from roots, leaves, and stems of the *in vivo* clone-5. Furthermore, molecular analysis showed that not all the transcript of the *rol* genes is polyTail. The levels of polyTail transcript of all *rol* genes are different in the diverse tissue of plantlets. The less amount of transcript, independently of the *rol* gene has been detected in leaf tissue. This behavior is not related with the culture conditions because the same trend has been found both *in vitro* and *in vivo*. Total amount of transcript did not differ among the tissue, as seen by *rolA* transcript, but it is different in *rolB* and *rolC* (Miano *et al.*, 2004). Grafting combinations with the transgenic clones as rootstocks were carried out with a nontransgenic cultivar and are under evaluation.

2.5.2 Transgenic plants for *osmotin* gene

After three growing seasons, the transgenic plants for the *osmotin* gene showed a compact phenotype with short internodes and reduced size of the leaves, exhibiting less vigor (Rugini *et al.*, 2000). The variation in the phenotypic characteristics was much more evident in the field-grown plants (Figure 6 and Table 4), probably due to the longer maintenance of the juvenility traits. In fact, in the greenhouse conditions, the low light intensity, responsible for a higher shoot elongation, and the constriction of the root system in the pot, may allow the plants to overcome the juvenility phase faster.

To check the possible acquired resistance to fungal pathogens, some transgenic plants were grown in pots under high humidity conditions together with plants affected by heavy symptom of *S. oleagina* (Cast). Hugh. The *in situ* localization of *osmotin* was performed by using a polyclonal primary antibody against osmotin jointed with a secondary antibody with alkaline phosphatase (AP) activity. The AP reaction in presence of nitro-blue tetrazolium chloride/5-bromo-4-chloro-3'-indolylphosphate p-toluidine salt (NBT/BCIP) substrate caused a purple color into the plant tissues. In transections of 1-year-old stems, coming from the apical internodes of field-grown plants, osmotin labeling was observed in epidermal and subepidermal tissues and, rarely, also in the most superficial layers of the cortical parenchyma. At

Figure 5 Semi-quantitative expression levels of Elongation Factor (E.F.), Glycosyl transferase (G.T.), and psb A, B, C, D between Canino wild type (w.t.) and Canino clone-5 (c5) from leaves and stems

cellular level, the protein was mainly localized around the vacuole (Figure 7). The signal was also present in the phloem and, mainly, in the cambium, but to a lesser extent than in the superficial tissues. In some cases, immature deutoxylem cells resulted were also labeled (D'Angeli *et al.*, 2001).

Inoculation tests for the presence of *S. oleagina* spots showed that one transgenic genotype seems to possess higher susceptibility than control plants (micropropagated and regenerated by somatic embryogenesis), whereas the other one shows a lower susceptibility. However, we cannot draw any conclusion since in these first phases of fungal infection the differences may be not completely defined (Table 5).

Figure 6 Transgenic plants of cultivar Canino for the *osmotin* gene showed a very compact phenotype and low vigor after three growing seasons

In transections of the apical third internodes of 1-year-old twigs from unstressed plants grown in the field, osmotin labeling was observed in the epidermal and subepidermal tissues and rarely, also in the most superficial layers (A–B) of the cortical parenchyma. At cellular level, the protein was mainly localized around the vacuole (C). The signal was also present in the phloem and, mainly, in the cambium (not shown), but at lower levels than in the superficial tissues. In some cases, immature deutoxylem cells were also labeled. No signal was ever observed in the unstressed leaves. Our results confirm the organ specificity of the protein accumulation controlled by a post-translation pathway able to negatively interfere with the gene constitutive expression of 35S promoter.

Table 4 Leaf and stem characteristics of the transgenic olive plants, cv. Canino, for the *osmotin* gene

	Osm 1	Osm 2	Control

3. FUTURE ROAD MAP

3.1 Potential Applications of Gene Transfer for the Genetic Improvement in Olive

Genetic transformation programs in this genus are focused on solving the main agronomic and commercial problems by transfer of one or more foreign genes or to limit the expression of the endogenous ones. Large availability of genes is essential to start a good program of genetic improvement by this technology, both from olive species and from other species or genera. About 400 sequences have been deposited in the GeneBank up to now (Table 1).

3.1.1 Fruit ripening and oil quality

The regulation of fruit ripening and the increase of oil content and quality are of much interest, since many cultivars ripen early and have fruits with high water content and early fruit drop. This pattern may be corrected by generating transgenic plants with a reduced ethylene biosynthesis, by using an antisense gene. The introduction of antisense genes for blocking ethylene synthesis (Oeller *et al.*, 1991)

or for reducing polygalacturonase activity (Smith *et al.*, 1988) could be useful.

With regard to the oil quality, two molecular strategies can be used to modify the oil composition and content: the alteration of the major fatty acid levels by suppressing or expressing a specific key enzyme in lipid biosynthesis and/or the creation of an unusual fatty acid. Stearoyl-acyl carrier protein denaturase is the key enzyme for the conversion of saturated stearic acid (C18:0) to mono-unsaturated oleic acid (C18:1), the main component of olive oil and responsible for its high dietary value (Baldoni *et al.*, 1996). Temporal and transient expression of the S-ACP denaturase gene has been studied during fruit development (Haralampidis *et al.*, 1998), and its expression is developmentally regulated with earlier expression in embryos than in mesocarp. By antisense suppression or co-suppression of oleate denaturase it was possible to increase oleic acid (C18:1) from 24% to 80% in the transgenic soybean (Kinney, 1995, 1996a, b, 1997; Yadav, 1996) and in *Brassica* seed by the antisense expression of a stearoyl-ACP denaturase gene (Knutson *et al.*, 1992). The same strategy was adopted to increase stearate acid (C18:0) by up to 30% both in canola and rapeseed (Auld *et al.*, 1992; Falco *et al.*, 1995). Unusual fatty acids can be produced in one plant by transferring a gene encoding the specific biosynthetic enzyme. An example can be seen in canola, which naturally does not produce laurate (C12:0), while a new transgenic genotype does contain laurate. The oil content of some nut crops used for cosmetics, such as almond, could be increased or their composition could be modified by these techniques. The oxidative stability of the oleic acid in soybean oil can be also improved as reported by Ellis *et al.* (1996).

3.1.2 Parthenocarpy

A major limiting factor for olive productivity is the alternate bearing and often the lack of pollination that causes this problem in areas with less intensive olive cultivation. Olive shows some tendency to natural parthenocarpy under some environmental conditions, although the fruits remain very small because they do not develop normally. Genes inducing parthenocarpy would permit the development of parthenocarpic fruits with regular size, and would overcome the problem related to self-sterility among olive cultivars. Self-sterility is under the control of the placental-ovule-specific *defh9* gene regulator sequence, expressed during early flower development. The introduction of the parthenocarpy gene of *Arabidopsis* may allow fruit development and subsequently boost the yield, and may help to overcome the pollination problem as already successfully tried in eggplant (Rotino *et al.*, 1997). In addition, the reduction of flower numbers observed in kiwi may contribute to solve the waste of energy and to reduce the alternate bearing (Rugini *et al.*, 1997).

3.1.3 Abiotic stress tolerance

Cold hardiness is a very important objective for olive improvement (Bartolozzi and Fontanazza, 1999). Transformation could involve the antifreeze protein (Hightower *et al.*, 1991), the overexpression of the superoxide dismutase gene, which permits the repair of frost-damaged cells (McKersie *et al.*, 1993; Van Camp *et al.*, 1994), and the overexpression of *Arabidopsis CBF1* gene enhances freezing tolerance by inducing genes associated with cold acclimatization, and could also be useful in olive too (Jaglo-Ottosen *et al.*, 1993).

3.1.4 Plant architecture

Another possibility offered by biotechnology for modifying the growth and reproductive behavior is the modification of plant receptors in order to change the light perception. The transformation with phytochrome genes (*phyA*, and/or *phyB*, sense or antisense), which together with other photoreceptors control plant development (circa-

dian rhythms, apical dominance, blossoms, growth and fruit ripening, photosynthesis products distribution, development of photosynthetic systems, transpiration control, and hormone synthesis), may contribute to develop plants with high agronomic value and suitable for very high density planting (Tucker, 1976; Vince-Prue and Canham, 1983; Baraldi *et al.*, 1992; Muleo and Thomas, 1993, 1997).

3.1.5 Resistance to pathogens and pests

The challenge of using biotechnologies in this area is to generate broad resistance mechanisms that have been difficult to achieve with classical breeding approaches. The use of antifungal genes or a pool of genes may be effective for improving resistance to fungal diseases, particularly *Verticillium* wilt and *S. oleagina*. *Osmotin* gene, *protein inactivating ribosomes* genes (Longmann *et al.*, 1992), *stilbene synthase* gene (Hain *et al.*, 1993), hydrolytic enzymes such as *chitinase* and *glucanase* (Broglie *et al.*, 1991; Yoshikawa *et al.*, 1993), *glucose oxidase* gene (Wu *et al.*, 1995), and polygalacturonase (*PGIPs*) that inhibit the activity of endo-polygalacturonases released by fungi on invasion of the plant cell wall could improve the olive defense system.

Regarding bacterial diseases, it is not so easy to introduce this kind of resistance into plants, because the product of the gene should act in the intercellular space; however, some species with enhanced resistance to bacteria have been obtained by introducing genes encoding bactericidal polypeptide, i.e., *thionin* (Carmona *et al.*, 1993), *attacin E* (Norelli *et al.*, 1994), the *synthetic analogue MB39* of cecropine (Mills *et al.*, 1994), and *cecropine* (Huang *et al.*, 1997). Particular attention should be paid to human lysozyme, which confers resistance to both fungi and to bacterium *P. syringae* in tobacco plants (Nakajima *et al.*, 1997).

The isolation of homologous genes from olive cultivars with low susceptibility to the fruit fly (*Bactrocera oleae*) is a potential way to achieve resistance to this pest in susceptible cultivars. Although, in the battle against insect attack, the *Bt* gene from *Bacillus thuringiensis* (Vaecck *et al.*, 1987) has successfully been introduced in other species with encouraging results, and could be an

alternative way to prevent olive fly damage. In addition, gene or genes isolation from resistant genotype, such as Bianca of Tirana should be attempted.

3.2 Expected Technologies

For olive transformation, the critical areas include the development of efficient regeneration protocols for elite cultivars, and the identification and evaluation of genes and specific promoters for useful traits.

Many potentially useful genes have already been isolated from several species, and could be introduced into olive separately or as multiples. The transformation selection procedure should be improved to increase public acceptance, possibly by replacing traditional selection markers (*nptII*) with other markers (*gfp*, *lecI*, *ipt*, *pmi*, *xyla*), although the percentage of escapes is quite high (>40%) in fruit crops (May *et al.*, 1995; Pena *et al.*, 1995, 1997; Mourgues *et al.*, 1998; Perl and Eshdat, 1998). Endo *et al.* (2001) suggested that the *ipt* gene from *A. tumefaciens* might be a suitable selectable gene. A multi-auto-transformation (MAT) vector, which combines the use of genes that stimulate growth and morphogenesis for positive selection of transformed cells with an excision mechanism to remove the markers and allow recovery of plants with normal phenotypes, could be very useful. The vector, which includes *ipt* and maize transposable element *Ac* for removing the *ipt* gene, seems to be promising (Ebinuma *et al.*, 1997). Other approaches might involve *xyla* (xylose isomerase) (Haldrup *et al.*, 1998) and *pmi* (phosphomannose isomerase) genes, both of which confer the capacity to use nonmetabolizable substrates. Finally, for highly regenerative cultures, it may be possible to eliminate the marker gene and select on the basis of physiological or morphological parameters, e.g., the response to toxins, culture filtrate, salt/drought resistance, etc. (Graham *et al.*, 1996).

1. INTRODUCTION

1.1 History, Origin, and Distribution

Almond, *Prunus dulcis* (Mill) D.A. Webb, is a stone fruit crop originated from one or more of the many wild species that evolved in the deserts and lower mountains slopes of Central and Southwest Asia, presently China and Iran. Today, we can still find many natural populations along the mountains from Tianshan in Kurdistan, extending across Turkistan, Afghanistan, and Iran (Felipe, 2000).

In spite of the ancient origin of almond culture, its wide distribution and economic importance, still not much is known about its origin, ancestors, or domestication place (Browicz and Zohary, 1996; Ladizinsky, 1999). It is believed that cultivated almond originated from spontaneous crosses among wild species, such as *Prunus fenziiana*, *Prunus bucharica*, and *Prunus kuramica*, among others, occurring in their local habitats where they coexisted, as suggested by several Russian botanists (Grasselly and Crossa-Raynaud, 1980). Another possible origin, however, could be the domestication of populations of *Prunus communis* L., with which *P. dulcis* shares numerous morphological characteristics (Kester *et al.*, 1991). In some regions, it is also possible that another ancestor, *Prunus webbii*, may have contributed, which is found wild in various regions in Balkans, Sicilian, and other Mediterranean areas (Godini,

1979; Socias i Company, 1998), including Spain (Felipe, 2000).

Independent of almond's origin, mankind played a major role in its breeding and dissemination. Almond populations growing close to civilization centers facilitated dissemination since its edible part happens to be its propagation unit. In this way, almond could easily spread from Central Asia to Persia, Mesopotamia and, profiting from the commercial routes, reach all the primitive civilizations (Kester *et al.*, 1991). The introduction in the Mediterranean area is thought to have occurred approximately 4000 years ago by the Phoenicians, followed by the Hebrews and the Greeks. Around 450 BC, almond culture spread from the Greek to the Mediterranean coast, and several important centers appeared in Portugal, Spain, France, Italy, Morocco, Tunisia, Greece, and Turkey (Kester and Ross, 1996).

Nowadays almond grows in countries bordering the Mediterranean sea, as well as in California where it was probably introduced in 1700 AD, in the Northwest of Mexico, in Chile, Argentina, South Africa, Australia, and western China (in Xinjiang province).

Until the 19th century, almond culture has not evolved much and the plants were propagated almost exclusively by seed, which led to the emergence of many different cultivars. Grafting is a practice with only some 150 years, which, however,

permitted to expand many different local cultivars selected by the farmers.

All around the world one can find several thousands of almond varieties being cultivated, with a high number in each country, where almond is a traditional culture. It is the case of Spain, with 200, Italy with 600, Turkistan with 2000, and even a small country like Portugal with over 150 cultivars (Monteiro *et al.*, 2003). In western China more than 40 almond cultivars have been described and used in almond production (Zhu, 1983), and so far over 100 genotypes have been found in Xinjiang province, where in old times the Silk Route connected China to the West (Socias i Company, 1998; Xu *et al.*, 2004).

1.2 Botanical Description

Cultivated almond appears in many references, even recent ones, with different denominations: *P. dulcis* (Miller) D.A. Webb., *Prunus amygdalus* Batsch., *P. communis* (L.) Archangeli, or even *Amygdalus communis* L. In 1768, the nomenclature *P. dulcis* L. was used for the first time for the cultivated almond producing sweet fruits, however, in 1964, because of the discrepancies occurring along the years concerning nomenclature, the General Committee for Botanical Nomenclature proposed the scientific name *P. dulcis* (Miller) D.A. Webb, accepting as synonym to those in almost all previously used classifications. According to *Flora Europaea* (1978), the botanical classification of almond is the following: family Rosaceae, subfamily Prunoideae, genus *Prunus* L., subgenus *Amygdalus* (L.) Focke, and species *dulcis* (Miller) D.A. Webb (*A. communis* L., *Amygdalus dulcis* Miller, *P. communis* (L.) Archangeli, *P. amygdalus* Batsch.) and *P. webbii* (Spach) Vierh.

Almond and peach (*Prunus persica* (L.) Batsch) are very close and hybridize easily. Often interspecific hybrids are found in places where both species grow (Felipe, 2000). Some of these hybrids are used as rootstocks in orchards, as it is the case of the clone GF-677 selected during the 1950s (Grasselly and Duval, 1997).

Almond tree is about 5–12 m high, has a strong root system with a plumbed root, white or pink flowers, and entomophilous pollination. Leaves are narrow, long, sharp-pointed, and denticulated.

In the northern hemisphere (examples given hereafter), flower initiation occurs around July and August, although this varies from year to year, not only among cultivars but also within the same cultivar, indicating that the process is under both endogenous and environmental cues (Lamp *et al.*, 2001). The flower buds are borne laterally in leaf axils on long shoots and shoot spurs. Flower buds enclose a single terminal flower and no leaves. One to several flower buds can form on a single spur (Lamp *et al.*, 2001). Almond flowers are hermaphrodite and have five fused sepals, five petals, a variable number of stamens (20–40), and one carpel with two ovules.

After floral induction, flower buds initiate floral organ differentiation, which is arrested usually around October when buds enter a dormancy period in preparation for autumn/winter. Promotion of dormancy seems to be independent of environmental signals. Budburst occurs mostly during winter and occasionally in spring (between January and March) depending on the varieties and locations as a consequence of dormancy breaking and usually before vegetative growth. Break of dormancy happens only after the chilling requirements, characteristic of each cultivar, have been fully satisfied. A recent study indicates that blooming time is a consequence of differences in chilling requirements among cultivars with only a small contribution from the heat requirements (Egea *et al.*, 2003).

Microsporogenesis occurs from November to January, depending on the cultivar, and ovary maturation occurs immediately after bloom (Rugini, 1986). When a pollen grain lands on a receptive stigma surface, it germinates and grows a tube that enters the style to ultimately reach the ovule. Gametophytic competition will favor genotypes with higher competitive abilities and result in the vigor of the subsequent sporophytic generation (Hormaza and Herrero, 1994).

As it happens in other Rosaceae and in the Solanaceae species, almond displays the gametophytic self-incompatibility system. Although not much appreciated by farmers, self-incompatibility is an important feature in fruit trees, ensuring outcrossing as the predominant mechanism for breeding, thus maintaining hybrid vigor. Self-incompatibility (SI) is controlled by a single multiallelic *S*-locus (De Nettancourt, 1977) coding

for RNase linked to S-locus (S-RNases) expressed in the pistil and for F-box proteins (SLF/SFB) expressed in the pollen (Ushijima *et al.*, 2003). The F-box proteins function as adaptors, interacting with self- and nonself-S-RNases differently, so that only the latter are driven to degradation via the ubiquitin/proteasome pathway (Kao and Tsukamoto, 2004). Therefore, S-RNases in self-(incompatible)-crosses remain active and able to degrade the pollen tube RNA, thus blocking its further growth.

Fertilization depends not only on the male gametophyte but also on the female gametophyte, the embryonic sac. In peach as in almond, despite the presence of two ovules, only one seed is usually produced. In peach, this is due to the fact that while one ovule grows following anthesis, the development of the other one is arrested (Arbeloa and Herrero, 1991; Rodrigo and Herrero, 1998). This situation was also suggested for almond since one ovule was consistently observed as much smaller than the other and both were still immature 1–2 days after pollination (Cortal *et al.*, 1999). Nevertheless, double kernels also occur, which is considered as a disadvantage for breeding. Double kernel formation is under genotypic and environmental control, with low temperatures at bloom being a major reason and justifying that earlier blooming flowers produce the higher number of double kernels (Spiegel-Roy and Kochba, 1981; Socias i Company and Felipe, 1994).

The almond fruit is a drupe, with a nonedible and green velvet skin covering the fleshy hull (exocarp and mesocarp, respectively). The shell (endocarp) can be from very hard (hard shell) to soft (paper shell) and, as already mentioned, contains one or two edible nuts. Twin seeds (developed within the same seed coat) may also form, and sometimes originate weak seedlings that were found to be haploids (Gulcan, 1975). Further studies have shown that low vigor twin seedlings are aneuploids (Martínez-Gómez and Gradziel, 2003).

Almond culture requires a hot and dry climate during summer, resisting well to drought when the rootstock is appropriate. Because of a high sensitivity to root anoxia, a good drainage is desirable.

The fruits are collected mechanically or manually by shaking the tree and the fruits with

a rod. The hull should be removed shortly after collection.

Almond trees have a juvenile phase of 3–4 years but in terms of production they are considered nonbearing until the fifth growing season, or 4 years after planting. An orchard can be productive for over 30 years.

Due to the repeated multiplication through seeds occurring under environmental conditions and natural selection, almond evolved in a way similar to forest species. Man also contributed to this evolution by successively selecting the best and larger seeds for growth. The conjugation of these two factors originated characteristic populations (ecotypes) corresponding to defined geographic regions (Felipe, 2000). Nowadays almond propagation is done by grafting on various rootstocks (mainly bitter almond, peach, and hybrids that usually provide higher vigor and yields). The plants for grafting are prepared in nurseries and planted during dormancy after 1 or 2 years.

Having a low chromosome number ($2n = 2x = 16$) almond has a relatively simple genome structure, with one of the smaller DNA contents per genome (0.54–0.55 pg/2C), similar to its close relative peach (Arumuganathan and Earle, 1991), which makes it an ideal species for molecular and genetic studies. For peach, Baird *et al.* (1994) reported a genome size of 290 Mbp (mega base pair) per haploid genome. The low chromosome number and the small genome size are features, in general, applicable to various *Prunus*, reason why they have been recommended as good models for woody species (Messeguer and Messeguer, 1998).

1.3 Economic Importance

Almond tree is grown for its edible fruits (seeds) that are industrially exploited in various countries with Mediterranean climate (Kester and Asay, 1975).

In the United States (California), almond orchards occupy an area that approaches 180 000 ha, reaching mean yields of 1800 kg nut ha⁻¹ in large irrigated farms, completely mechanized and mostly with a single producing cultivar. With much less almond growth area as compared to Spain (607 000 ha) or Tunisia (169 000 ha), California ensures much higher production (Kaska,

2001). According to the Food and Agriculture Organization (FAO, 2005), the top five almond producers in 2005 were the United States with 666 600 metric tons of nut (42% of the world's production), followed by Spain (204 500 t, 13%), Syria (130 000 t, 8%), Italy (105 312 t, 6%), and Iran (80 000 t, 5%). Although California's high yields (2378 kg ha⁻¹) are not as high as those of Syria (3174 kg ha⁻¹, with a total area of 21 000 ha) or France (2647 kg ha⁻¹ with an area of 1700 ha) (Kaska, 2001), the growth area and the productive conditions of California can offer a very homogeneous and attractive product associated with an efficient commercial organization strongly dedicated to the international market. These factors combined with a good stock management and capacity to regularly supply the consuming market in the presence of world prices that depend on the American currency, justify the Californian supremacy, even in years of reduced cropping (Monteiro *et al.*, 2003).

Almond world kernel production has reached 500 000 t/year in 2004, with United States being the main producer (1.3–1.5 t ha⁻¹), followed by Spain (1.0–1.2 t ha⁻¹). The other European countries are, by order of importance, Italy, Greece, Portugal, and France, representing a very low production level (FAO, 2005). The fact that United States produces soft shell almonds strongly contributes to the high shelling percentage (30–50% shelling for semi-soft and 50–70% for paper shell) as compared to countries where hard shell varieties are grown (10–30% shelling) (Socias i Company *et al.*, 2007).

In 2005, Australia contributed with 16 500 t of kernel (2390 t ha⁻¹ of bearing trees). However, the Australian Almond Board expects to double this value by 2008 since from the total planting area, approaching 13 759 ha, about half was younger than 3 years and still nonbearing (Almond Board of Australia, 2006). Profiting from an optimized irrigation drip system and nutritional program, yields up to 3900 and 4602 kg ha⁻¹ were obtained with “Nonpareil” and “Carmel”, respectively (Kennedy, 2006).

In contrast to Australia and California, where almond is grown in intensive and irrigated system, most production in Spain (90%) and other Mediterranean countries is still largely traditional and unirrigated, although in certain areas there are newly established and high producing orchards (Cordeiro and Monteiro,

2002). Concerted efforts in several European countries supported launching almond culture in competitive conditions. For this purpose, organizations such as GREMPA (“Group de Recherches Méditerranéennes pour le Pistachier et l’Amandier”, former “Group de Recherches et d’Études Méditerranéennes pour l’Amandier”), FAO-CIHEAM dry fruits network (FAO-CIHEAM Inter-Regional Cooperative Research Network on Nuts), and also EU/Research Programs, have played a crucial role.

While Germany and Spain are the major markets of shelled almond (with 66 758 and 61 457 t, respectively), India is the largest global market for in-shell almonds, importing 25 785 t (corresponding to 94% of its consumption) (FAO, 2004). Most Indian imports are made from the United States but the preferred and more costly almonds are obtained from Iran and Afghanistan (Anonymous, 2004). Pakistan, China, and Lebanon are also big markets for in-shell almonds.

In European countries, almost all almonds are collected when they are completely mature (dry), which happens 6–8 months after full bloom. In most cases, only the kernel is used for consumption, but there is the exception of Turkey, Sicily, France, and a few countries in the Middle East and Scandinavia where the whole fruit is consumed collected a few weeks after blooming (Schirra, 1997; Felipe, 2000). The fruit hull has become commercially important as an animal feed, although initially it was only a by-product (Aguilar *et al.*, 1984).

Although the nutritional quality of almonds shows strong variations among cultivars (Socias i Company *et al.*, 2007), there are a number of characteristics that point to their high nutritional value for human consumption. Almonds have a high content of lipids, proteins, mineral salts, and vitamins (Souty *et al.*, 1971; Kester *et al.*, 1991; García-López *et al.*, 1996; Cordeiro *et al.*, 2001). Almonds have also been marketed as a good source of vitamin E, dietary fiber, and monounsaturated fat, the latter of which has been associated with decreased risk of heart disease (Spiller *et al.*, 1998). A good coverage of almond quality characterization and breeding for quality traits can be found in Socias i Company *et al.* (2007).

The almond kernel may be consumed raw or roasted, and when processed, it can be prepared

in many ways including as almond flour, salted, sliced, diced, in marzipan, nougat, ice cream, or almond milk, being used in snacks, cereals, confectionery, and desserts. The bitter or sweet oils extracted from almond kernel are often used in pharmaceutical industry and cosmetics. For direct consumption, usually only sweet almonds are used, as the bitter ones are toxic due to amygdalin, a cyanogenic glycoside they accumulate. The kernel also contains the enzyme amygdalase, which, by cell lysis and contact with amygdalin, processes it into benzylaldehyde and cyanide, which is poisonous (Schirra, 1997). The oil of bitter almonds, however, is much appreciated in food processing and in the pharmaceutical industry.

The wide variety of almond uses that evolved in different regions and cultures naturally entail different quality requirements (Socias i Company *et al.*, 2007).

1.4 Traditional Breeding

Almond is highly heterozygous and is one of the most polymorphic fruit species, due to its high SI and method of traditional culture using open-pollinated seedlings (Kester *et al.*, 1991; Socias i Company and Felipe, 1992; Socias i Company, 1998). Its broad genetic pool can be seen as an advantage for breeding, but it has also complicated the study of the species.

Up to now, the most important traits for breeding have been late flowering and self-compatibility as the more relevant for higher yield. These traits have required expensive and time-consuming progeny analyses, but in recent years they could have the support of biotechnology tools, specifically molecular markers, to assist in selection for earlier growth stages (for a recent review on almond genomics, see Martínez-Gómez *et al.*, 2006).

Grasselly and Olivier carried out crosses to obtain self-compatible descendants (Grasselly and Crossa-Raynaud, 1980). However, the first study on the transmission of self-compatibility in almond progenies was that of Socias i Company and Felipe (1977), who pointed out the heterozygosity of the self-compatible progenitor and the dominance of self-compatibility. Dicenta and García (1993b), by fluorescence microscopy, and Rovira *et al.* (1997), by fruit set, determined that SI is a monogenic trait with a multi-

allelic *S* series, the self-compatible allele (*Sf*) being dominant over the others. The SI-associated S-RNase genes represent an extreme example of allele polymorphism. Extensive studies have been conducted in almond for characterization of S-phenotypes by analysis of stylar S-RNases using nonequilibrium pH gradient electrophoresis (NEpHGE) of proteins produced in pistils collected prior to blooming (Basković *et al.*, 1997; Ballester *et al.*, 1998) and S-genotypes (DNA extracted from young leaves to analyze S-RNase genes) as well as for identification of a number of new alleles (Ma and Oliveira, 2001a, b, c, 2002; Certal *et al.*, 2002) (for an update see Martínez-Gómez *et al.*, 2006). Also, the transmission of *S*-alleles to the offspring was studied by NEpHGE and correlation of the S-proteins with the almond SI alleles (Batlle *et al.*, 1997; Basković *et al.*, 1997, 1998, 1999). Breeding strategies capable of ensuring self-compatibility in the offspring have been supported by different methods of analysis, namely, fluorescence microscopy, stylar ribonuclease assay, and *S*-allele PCR (polymerase chain reaction) (Bošković *et al.*, 1999; Tamura *et al.*, 2000; Ortega and Dicenta, 2003).

In most breeding programs aiming to introduce self-compatibility, the almond breeders have used Tuono, a self-compatible almond variety (Batlle *et al.*, 1997; Egea *et al.*, 2000; Duval *et al.*, 2001; Socias i Company *et al.*, 2004). Tuono is originally from Italy, from the region of Apulia where other *Prunus* such as *P. webbii* coexist. Because *P. webbii* is reported as self-compatible (SC) species, it has been assumed that SC trait was introgressed in almond from this wild relative (Godini, 1979, 2000), probably through *Sf* (Socias i Company, 2002), however, this has not yet been proved. Moreover, some data have shown that *P. webbii* carries S-RNase genes, and that only some accessions carry the *Sf* gene (Sánchez and Oliveira, 2005). Tuono has the *Sf* genotype, where *Sf* presumably confers self-fertility. The *Sf* allele has been identified in Tuono and this allele segregates with self-compatibility, with no RNase activity linked to *Sf* (Bošković *et al.*, 1999; Ortega and Dicenta, 2003). The *Sf* gene sequence was isolated from Tuono (Channuntapipat *et al.*, 2001; Ma and Oliveira, 2001c), however, the actual causes of SC remain unknown. According to Vargas *et al.* (1998) there are around 30 self-fertile almond cultivars worldwide, although none is widely cultivated.

Blooming time is another very important trait in almond, since this species has shown the earliest blooming time among all the fruit tree species. Early bloom restricted almond growing to regions with a low risk of winter/spring frosts. However, over centuries of almond growing, its culture has expanded into inland regions where the occurrence of winter/spring frosts is common. Thus, late blooming has become an important trait in almond breeding programs that attempt to develop later blooming cultivars to avoid frost damage. Breeding for late blooming has been conducted by numerous researchers (Kester, 1965; Grasselly, 1972; Vargas *et al.*, 1984; Socias i Company *et al.*, 1998a), and the transmission of this character in progenies has been studied (Kester *et al.*, 1973, 1977b; Dicenta *et al.*, 1993a). Blooming time is considered to be inherited quantitatively in most fruit species and most results confirm this type of transmission in almond. However, Kester (1965) suggested that in some progenies of the late-blooming budsport “Tardy Nonpareil”, a single dominant gene could be involved in determining the blooming date, since a bimodal distribution of blooming dates was observed among the seedlings obtained. A selection derived from “Tardy Nonpareil” was used to follow the transmission of the late-blooming allele for several generations and similar segregation patterns were found, confirming the dominance of the mutated allele (Grasselly, 1978). Thus, blooming time in almond seems to be determined by a major gene *LATEBLOOMING* (*Lb*), with late bloom dominant over early bloom, and by modifier genes inherited quantitatively.

The *Lb* gene was mapped using the progeny from a cross between “D-3-5” (a *Lb/lb* heterozygous genotype) and “Bertina” (a Spanish cultivar with unknown origin) (Ballester *et al.*, 2001) and was found to be located on the *Prunus* linkage group 4 (G4). Furthermore, blooming time has been studied as a quantitative character in an intraspecific peach F₂ population by Dirlewanger *et al.* (1999), in an interspecific (*P. persica* × *Prunus ferganensis*) backcross by Verde *et al.* (2002) and in the F₂ of the interspecific cross between the almond variety “Texas” and the peach variety “Earlygold”, by Joobeur (1998). Two candidate genes putatively involved in almond flowering have been assigned in the *Prunus* genome to linkage groups corresponding to the regions where two

quantitative trait loci (QTLs) for blooming time were detected (Silva, 2005; Silva *et al.*, 2005). However, to date, both the sequence and the specific function of *Lb* genes responsible for the blooming time QTLs remain unknown. One additional flowering time candidate gene was co-located with the position of the *Evergrowing* gene, which determines a nondeciduous behavior in peach (Silva *et al.*, 2005).

Other breeding goals have focused on tree behavior and on kernel quality. Breeding for a high fruit set apparently depends on a high number of factors, such as efficient pollination, flower fertility, and the maximum number of fruits that a tree can bear (Socias i Company *et al.*, 2004, 2005), although it has been suggested that in general, blooming density is a reliable indicator of the productivity (Sánchez-Pérez *et al.*, 2007b). Blooming density and productivity have been studied by Grasselly (1972), Kester and Asay (1975), Grasselly and Crossa-Raynaud (1980), Vargas *et al.* (1984), Dicenta *et al.* (1993a), and Socias i Company *et al.* (2004). However, only few studies have been performed regarding another important character, ripening time (Grasselly, 1972; Kester and Asay, 1975; Dicenta *et al.*, 1993b, 2005). On the other hand, there are many studies regarding the transmission of kernel traits including kernel weight, shell hardness, kernel percentage, double kernels, and kernel bitterness (Grasselly, 1972; Spiegel-Roy and Kochba, 1974, 1981; Kester *et al.*, 1977a; Vargas *et al.*, 1984; Dicenta and García, 1993a; Dicenta *et al.*, 1993b; Socias i Company and Felipe, 1994; Martínez-Gómez *et al.*, 2006). Bitterness was characterized as a monogenic trait, the bitter genotype being recessive (Heppner, 1923, 1926; Dicenta and García, 1993a; Vargas *et al.*, 2001; Martínez-Gómez *et al.*, 2006). Kernel bitterness is independent of the fertilizing pollen, instead being the result of the mother tree genotype and of the transportation of precursors from the leaves to the seed (Socias i Company *et al.*, 2007). In Australia, to understand control and improvement of the flavor of almond kernels, markers are being searched to identify the bitter or marzipan characters in breeding progenies (Wirthensohn, 2006).

As reported by Socias i Company *et al.* (2007), the present tendency is to improve almond varieties having specific quality traits for various applied

purposes. These authors have gone in detail through the different quality goals that breeders may target, from physical traits (kernel size, kernel shape, seed coat, double and twin kernels, and fruit hull) to biochemical characteristics (cyanoglucosides, phenolics, vitamins, and minerals, lipids, proteins, carbohydrates, fibers, and allergens). In most cases, the quality characterization of different varieties studied at regional level has not been conducted using uniform evaluation methods and therefore, is inconsistent (Socias i Company *et al.*, 2007). The resulting meager knowledge about the genetic control of the existing variability creates an obvious breeding difficulty. Moreover, to have a breeding strategy directed toward special product applications means that different varieties may be selected for different uses and that a separation must be ensured in collection, storage, processing, and commercialization routes.

Another target for breeding includes disease resistance, although almond is usually considered as challenging for a variety of diseases. Viruses from the Bromoviridae family, such as calico (infectious bud failure) caused by *Prunus* necrotic ringspot virus, or Prune dwarf virus cause systemic diseases in almond and other *Prunus* species. Viral diseases are, in most cases, insufficiently characterized, and no resistant varieties have been reported. Bacterial, phytoplasma and fungal diseases are also damaging in almond orchards. This is the case of bacterial spot (caused by *Xanthomonas campestris* pv. *pruni*) or brown rot, a common disease in fruit species (caused by *Monilia laxa*), leading to the decline of young branches especially in a wet spring. Anthracnose (caused by *Colletotrichum acutatum*) infecting blossoms, leaves, fruits, and small branches, was recently reported as a problem in the new almond orchards in Australia (Hall *et al.*, 1998) and also reported since 1995 as infecting numerous varieties in United States including “Nonpareil” (Adaskaveg *et al.*, 1999). Among the fungi affecting almond roots *Phytophthora* (particularly in clay soils), *Verticillium dahliae* and *Armillaria* are the most damaging. The use of appropriate rootstocks, with reduced susceptibility to these fungi, has been a good strategy to prevent negative effects in the scion (Grasselly and Duval, 1997). Almond scab, a disease caused by *Venturia carpophila* (*Fusicladium carpophilum* as imperfect form) and also affecting peach, plum, and apricot, can be very serious in

some regions leading to complete necrosis of the smaller branches.

The fungus *Phomopsis amygdali* (Del.) Tuset and Portilla (*Fusicoccum amygdali* Delacr. as imperfect form) is responsible for *Fusicoccum* canker or constriction canker, a disease responsible for important economic losses in almond orchards around the Mediterranean region (Cabrita *et al.*, 2004). *Fusicoccum* affects mainly twigs of the lower part of the trees, causing canker on shoots and necrosis on leaves (Barbé, 1993). This disease is favored mainly by high nitrogen levels in the soil and by wet weather, since it is transmitted just by rain. The diffusion of this disease is very slow but its eradication from an orchard is very difficult and expensive (Romero and Vargas, 1981). Because it takes several years for the plant to develop symptoms, the development of molecular markers linked to the tolerance/sensitivity phenotype could be of high value for breeding purposes and some studies have been conducted to meet this goal (Martins *et al.*, 2001, 2005; Cabrita *et al.*, personal communication). Additionally, the identification of specific alleles of resistance genes (R genes) from very tolerant varieties, may allow the development of markers exploitable in marker-assisted selection (Martins and Oliveira, 2005).

There are several almond breeding programs presently running worldwide. In Spain, three programs are being developed, in Reus, Zaragoza, and Murcia. The Reus program, conducted at IRTA, Mas Bové has focused on early selection performed during the 2nd to 5th growth years. Characters like leafing date (related to flowering time in early medium blooming varieties), vigor, growth, and branching are analyzed in the 2nd year, while blooming date, early cropping production, nut characteristics, self-fertility, and some disease sensibilities, are assessed in between the 3rd and 5th years (Vargas *et al.*, 2005). The breeding program of Zaragoza was focused on obtaining self-compatible and late-blooming cultivars (Socias i Company, 1990; Felipe, 2000). However, this program is continuing to obtain better performing cultivars, characterizing selections in relation to some flower traits and evaluating their self-fruitfulness based on the efficiency of their pollen tube growth and on the stigma/anthers position (Socias i Company *et al.*, 1998b). Main focus at present is directed to improve nut quality, based on multivariate

analyses of chemical components, assuming that a similar biochemical composition will result in similar commercial, industrial, sensorial, and nutritional qualities (Kodad, 2006; Socias i Company *et al.*, 2007). In Murcia, the main aim is to obtain self-fertility and late flowering to allow almond production in the inner and colder regions of Spain. The breeding program in Murcia is being assisted by molecular markers to fasten discarding self-incompatible varieties (Sánchez-Pérez *et al.*, 2004). The molecular identification of almond bitterness will also be implemented for regular application within a couple of years (F. Dicenta, 2006, personal communication).

The American almond breeding program has been directed to introduce self-fertility, improved growth habits, drought resistance, and kernel quality, using germplasm improvement, propagation techniques, and molecular markers (Gradziel *et al.*, 2001; Martínez-Gómez and Gradziel, 2002).

In Australia the breeding program started in 1997, aiming to produce superior scion and rootstocks adapted to local conditions (Sedgley *et al.*, 2002). Classical hybridization for improved nut and quality ranking is being combined with molecular breeding (for self-fertility, genetic fingerprinting, genome mapping, and transformation) and with pathological analyses for viruses and anthracnose (Sedgley *et al.*, 2002).

The availability of good molecular markers can make it easier to plan crosses in a breeding program, maximizing genotypic differences that often are not noticed at phenotypic level. Markers also make it possible to organize the germplasm in genetic pools, thus facilitating choices and considerably reducing the number of crosses requiring evaluation, and advance hybrid combinations to perform.

As a useful tool for breeding projects, a saturated linkage map (*Prunus* reference map) of 246 markers was constructed for an almond (cv. "Texas") × peach (cv. "Earlygold") F₂ progeny within a European project (Joobeur *et al.*, 1998). New markers have been added to this map (Aranzana *et al.*, 2003; Dirlewanger *et al.*, 2004; Howard *et al.*, 2005) and it now has 826 markers including 449 simple sequence repeats (SSRs), 361 restriction fragment length polymorphisms (RFLPs), 11 isozymes, and 5 sequence tagged sites (STSs) (P.

Arús, personal communication). These markers span a total distance of 524 cm with an average density of 0.63 cm/marker (Howard *et al.*, 2005) and a maximum interval of 7 cm (P. Arús, personal communication). The existence of the T×E map has been very useful for the *Prunus* research community, providing a highly polymorphic population for linkage studies and establishing a common terminology for linkage groups. The T×E map provides a set of transferable markers (anchor markers) of known map position that have facilitated the development of framework maps in others crosses. It has also allowed the location of different major genes and QTLs in a unique map, the search for markers to saturate specific genome regions or the establishment of map comparisons with other *Prunus* species. In fact, a recent study on comparative mapping, led to the conclusion that, at the genome level, the *Prunus* genus can be treated as a single genetic entity (Dirlewanger *et al.*, 2004).

Other maps have been constructed, namely using a cross between Nonpareil and Lauranne (Gregory *et al.*, 2005) or R1000 (a French cultivar) and Desmayo Langueta (Sánchez-Pérez *et al.*, 2007a).

The availability of expressed sequence tag (EST) collections is another feature that strongly facilitates the genetic and molecular analyses, especially in perennial trees. A growing collection of peach and almond ESTs has been released to public databases. The collection includes 9984 ESTs from a peach mesocarp complementary DNA (cDNA) library and 2794 ESTs from an almond developing seed cDNA library. A Rosaceae database has been recently created (including for instance genetic and physical maps, ESTs, bacterial artificial chromosomes (BACs), and markers) assembling a wide amount of genetic and molecular information and making it available to researchers working with this family (Genome Database for Rosaceae, GDR; <http://www.bioinfo.wsu.edu/gdr>) (Jung *et al.*, 2004).

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

Viruses are among the most difficult to eliminate disease agents. Although a virus disease damaging

to other Prunoideae as plum pox (responsible for sharka disease) is not known for almond, the establishment of new orchards with healthy certified trees does not guarantee virus eradication for long periods. Viruses from the Bromoviridae family (*Ilarvirus* genus), including Prune dwarf virus (PDV) and *Prunus* necrotic ringspot (PNRSV) are among those that spread rapidly in an orchard, even with good orchard management practices. PDV and PNRSV are transported through pollen, profiting from a living host and from a special delivery system—the pollinator insects, making cross-pollination (obligatory for seed set) a common source of infection. As recently observed by *in situ* reverse transcriptional-PCR, PDV aggregates inside the pollen grain forming a ring surrounding the vegetative and the germinative nuclei (Silva *et al.*, 2003). In spite of the infection, the pollen grain is able to germinate on a receptive stigma (Nyeki and Vertesy, 1974) and this allows the virus to colonize the pollinated tree. It is known that these viruses are able to infect a new orchard in less than 3 years causing dwarfism and various unquantified damages. Control of virus propagation through genetic engineering is at present one of the most efficient strategies achievable in most cases by the use of viral genes, such as coat protein genes or genes coding for movement proteins (for a revision on strategies to block virus proliferation see for instance Yadav *et al.*, 2005).

The fact that damage by virus infections has not yet been quantified in almond orchards, leads to the supposition that either the damage is not too severe, or perhaps it has not yet been possible to maintain clean orchards as control. Nevertheless, the strategy of genetic engineering for virus resistance (PDV) has been studied to understand possible mechanisms to interfere with the virus replication (see Section 2.1).

An important breeding goal eventually achievable through genetic engineering is self-compatibility for elite cultivars. With this strategy it would be possible to retain the nut quality and characters already accepted in the market while profiting from a minor modification that would allow the farmers to spare pollinator bees, pollenizer trees, and associated problems. Efficient pollination is crucial for seed set and for instance in California, shortage of honeybee colonies

due to mite (*Varroa destructor*) infestations has been a major constraint in almond production (Holden, 2006). Over 1 million honeybee colonies are needed to pollinate the 180 000 ha of almond orchards. In parallel to the programs attempting to obtain self-compatible cultures through conventional breeding, the use of genetic engineering may be important when production relies on one or few cultivars. For instance, California production is mainly ensured by a few cultivars, “Nonpareil” (38%), “Carmel” (17%), and “Butte” (11%) (data from 2004) (Boriss and Brunke, 2005). Although with a much smaller growth area, the situation in Australia is similar, with “Nonpareil” ensuring 51% of the production (Australian Almond Planting Report, 2006). Breaking down SI in these varieties would be possible by a transgenic approach using antisense technology or RNA interference, to block the expression of one of the S-RNases. Such a strategy would allow the farmers to avoid the use of pollenizer trees, thus having the chance of dedicating the whole farm area to the variety of their choice. However, considering what happens in orchards with self-compatible cultivars, it is not clear if pollinating bees would not still be needed. If honeybees could be avoided, a better control of virus diseases might be attainable.

2. DEVELOPMENT OF TRANSGENIC ALMONDS

2.1 Donor Gene and Transgene Construction

There are very few reports on almond transformation, and with the exception of the use of *rol* genes, all of them only mention the use of marker genes. Other genes of interest have not yet been introduced in almond. As reporter genes, the β -glucuronidase gene (*gusA*) under the control of CaMV 35S signals (promoter and terminator) was used (p35SGUSint plasmid) by a number of authors (Archillecti *et al.*, 1995; Miguel and Oliveira, 1999; Ainsley *et al.*, 2001a; Costa *et al.*, 2006). The luciferase (*luc*) gene under the control of 35S promoter and the Nos terminator was also employed in plasmid pAL23 (Miguel, 1998). Recently, a green fluorescent protein gene, with modified codon usage and designed to be

targeted to the endoplasmic reticulum (*mgfp-5-ER*) (Haseloff *et al.*, 1997), was also used with the 35S promoter and the Nos terminator (plasmid pBI121mgfp-5-ER) (Ramesh *et al.*, 2006).

As selectable marker genes, neomycin phosphotransferase (*nptII*) (with the Nos promoter and terminator) was used to achieve tolerance to kanamycin (Archilletti *et al.*, 1995; Ainsley *et al.*, 2001a). The herbicide R gene phosphinotricine acetyltransferase (*bar*) was used together with hygromycin phosphotransferase (*hpt*) both under the control of 35S promoter and Nos terminator sequences (plasmid pWRG2426) (Miguel, 1998). The use of phosphomannose isomerase gene (*pmi*) under the control of CPMS promoter (cestrum yellow leaf curling virus promoter—short version) and Nos terminator has also been reported (plasmid pNOV2819 *manA*) (Ramesh *et al.*, 2006).

Production of transgenic roots has been obtained by infection of microcuttings with *Agrobacterium rhizogenes* 1855 NCPPB and the transfer of *rol* genes was confirmed by Southern blot analysis (Damiano *et al.*, 1995).

The different transformation experiments conducted in almond are summarized in Table 1.

Studies aiming to identify good constructs for almond engineering for disease control, however, have also been conducted. In this case, virus diseases have been targeted, specifically the *Ilarvirus* (Bromoviridae) PDV (Raquel *et al.*, 2005). The gene constructs, based on the coat protein gene sequence of a PDV strain isolated from infected almond plants, were prepared from the viral RNA4, cloned in intermediate vectors (pCRII, through TA-cloning) and inserted in pGREEN vectors (JIC) (Hellens *et al.*, 2000) for plant transformation. Until present the gene constructs, driven by the CaMV 35S promoter, were only tested in the transformation of a model host plant (*Nicotiana benthamiana*) (see Section 3.1).

2.2 Transformation Methods Employed in Almond

For successful genetic transformation, the transforming nucleic acids have to travel across the cell wall (except when protoplasts are used), the plasma membrane, and the nuclear envelope, without

compromising cell viability. Although several transformation methods are available for plants (Oliveira *et al.*, 1996), *Agrobacterium*-mediated gene transfer, biolistic DNA transfer and, to a less extent protoplast-based direct gene transfer, are the major techniques used in virtually all transformation work aimed at direct production of improved cultivars (Siemens and Schieder, 1996; Birch, 1997).

2.2.1 *Agrobacterium*-mediated transformation

Almond tissues have been shown to be susceptible to infection by *Agrobacterium* (De Cleene and De Ley, 1976) and *Agrobacterium*-mediated transformation has been the method of choice for transformation experiments in almond.

Agrobacterium tumefaciens infection of almond leaf explants has been performed following procedures such as wounding the leaves with a scalpel previously dipped in bacterial suspension (Miguel and Oliveira, 1999; Costa *et al.*, 2006) (Figure 1a–d) or immersion (a few seconds to 1 h) of wounded leaves (Miguel, 1998) or leaf pieces (Archilletti *et al.*, 1995; Ainsley *et al.*, 2001a; Ramesh *et al.*, 2006) in the bacterial suspension. In the case of immersion of wounded leaves, leaf explants were wounded either by transversal cuts across the midrib or by particle bombardment (BIORAD PDS-1000 He) with 1.6 μ m uncoated gold particles and 1300 psi of helium pressure (Miguel, 1998). The type of infection method has been shown to affect mainly the leaf regeneration ability and in the case of “Boa Casta” seedlings, the infection method involving the wounding of leaves with a scalpel dipped in the bacterial suspension was chosen (Miguel, 1998). In this method, the leaves are incompletely sectioned (Figure 1a), and the bacteria released in the wound area are observed contacting the epidermal and mesophyll cells (Figure 1b) and penetrating through the close-by stomata (Figure 1c). The *Agrobacterium* virulence status is also confirmed by the formation of the typical cellulose fibrils (Figure 1b). This infection method has the advantage of preventing full contact of the explant with the bacterial suspension. Instead, only transformation-competent areas, consisting of the cells surrounding the wounds, are infected by

Figure 1 Early stages in the transformation of almond leaves. (a–d) Scanning electron microscopy (SEM) aspects of: (a) the abaxial surface of a leaf wounded by scalpel (*bar*: 100 μ m), (b) detail of *Agrobacterium* EHA105 attached to the plant cells and with the typical cellulose fibrils, (c, d) aspects of bacteria at the wound and also entering through the stomata. (e) Light microscopy image of leaf sections to reveal the wound site and the area reached by *Agrobacterium* (detail in bottom insert) 3 days after co-cultivation, and a control leaf (top insert) with profuse intercellular spaces. Leaf orientation is displayed as in the culture medium (abaxial side up). (f) GUS assay performed 1 week after co-cultivation and showing that GUS positive cells occur all across the leaf (indicated by a dotted line). (g) SEM image showing the proliferation of meristematic centers (at various stages) in the dedifferentiating leaf (*bar*: 100 μ m). (h) Emergence of two buds initials and aspect of the vascular connection linking the more developed bud to mother tissue vessel (arrows). (i–k) Transient expression analyses assessed 24 h after particle bombardment, to monitor the transfer of the GUS gene (i), or the luciferase (j, k). Bars: 1 μ m: (b), 10 μ m: (c) and (d), 100 μ m: (a), (e)–(h), 5 mm: (i)–(k)

Agrobacterium (Figure 1e–f). Since the regeneration of adventitious shoots also occurs preferentially from these areas (Figure 1g, h), no additional stress needs to be imposed on the remaining explant cells.

In general, woody species are difficult to transform and some strategies have been designed to improve transformation efficiency, such as the addition of acetosyringone (AS) during co-cultivation. AS has been applied, for instance in apple, kiwifruit, and citrange (James *et al.*, 1993; Janssen and Gardner, 1993; Cervera *et al.*, 1998) with the aim of stimulating transcription of *Agrobacterium* virulence genes. In almond, AS was used in the *Agrobacterium* growth medium prior to infection (Miguel, 1998; Miguel and Oliveira, 1999; Ramesh *et al.*, 2006). However, in the experiments of Costa *et al.* (2006) AS was employed in a different way, being added to the plant culture medium at a concentration of 150 μ M during the whole preculture, co-cultivation, and induction period (3, 3, and 21 days, respectively), with a clear positive effect. Actually the combination of AS treatment with a modified selection scheme allowed increasing the transformation efficiency by a 100-fold (Costa *et al.*, 2006).

In *Agrobacterium*-mediated transformation different strains have been used, namely EHA105, LBA4404, and AGL1 but regeneration of transgenic plants has been reported only with EHA105 and AGL1 (Miguel and Oliveira, 1999; Costa *et al.*, 2006; Ramesh *et al.*, 2006). Both EHA105 and AGL1 are of the succinamopine type, supervirulent, derived from C58 strain and carry the virulence plasmid pTiBo542, while LBA4404 is an octopine strain carrying pLBA4404. The high transformation ability of pTiBo542 has been previously demonstrated for a number of plants and correlated with a higher expression of the *vir* genes, especially *virG* (Liu *et al.*, 1992; Ghorbel *et al.*, 2001 and references therein).

When comparing the strains EHA105 and LBA4404 at least a threefold increase in the mean number of β -glucuronidase (GUS)-expressing spots per leaf was observed with EHA105 (Miguel and Oliveira, 1999). For the induction of rooting, *A. rhizogenes* 1855 NCPPB was successfully used on almond cuttings as confirmed by the hairy root phenotype observed and positive results in Southern blot analysis (Damiano *et al.*, 1995).

2.2.2 Transformation by particle bombardment

Microprojectile bombardment of almond leaf tissues has been tested as an alternative transformation method using the electric discharge particle acceleration device ACCELLTM technology (Agracetus, Middleton, USA) (McCabe and Christou, 1993) or a handgun device (John Innes Centre, Norwich, UK) (Miguel, 1998). It has been stated that the ability to deliver foreign DNA into regenerable cells, tissues, or organs, appears to provide the best method for achieving truly genotype-independent transformation in agronomic crops, bypassing *Agrobacterium* host-specificity (Christou, 1995). Due to the physical nature of this process, there is no biological constraint to the actual DNA delivery. However, in particular cases, in which recovery of transgenic plants has not been reported, the main problem appears to be the absence of a favorable regeneration response and not a problem in the DNA delivery method (Christou, 1995).

For transformation of almond leaf explants, specific bombardment parameters were selected after a series of transient expression assays for *gusA* and *luc* reporter genes (Figure 1i–k). Due to the importance of targeting the appropriate cells that are simultaneously able to be regenerated and transformed, the depth of penetration becomes one of the most important variables. Particle size and, to a less extent, the impact of the acceleration force that determines particle velocity (Bilang *et al.*, 1993), are determinant factors for the depth of tissue penetration, but the number of viable cells as a result of injury also has to be considered. Since adventitious shoot initials in almond leaves, seem to develop from the inner cell layers (Figure 1f–h) (Miguel, 1998), the bombardment parameters used were those allowing the deeper penetration of tissues without causing too much damage, specifically using 14 kv with ACCELLTM equipment and 350 or 400 psi with the handgun, with gold particle sizes of 0.95 or 1.3 μ m.

Transient expression was observed after bombardment (Figure 1i–k) but no stable transformants were obtained even though the regeneration ability of leaf explants seemed not to be affected by the bombardment process as evaluated by the control explants (bombarded with uncoated

particles) (Miguel, 1998). This may indicate that the *Agrobacterium* functions of transfer DNA (T-DNA) targeting to the nuclear genome may be important for the success of almond transformation. However, the fact that in biolistics transformation the transforming DNA is spread through the whole leaf and not specifically targeted to the organogenic regions may also justify the inability of this method to yield transgenic plants.

2.3 Selection of Transformed Tissue

For selection of transformed tissue, several selective agents have been reported including kanamycin, hygromycin, and phosphinothricin. Also, a positive selection strategy using mannose, to select for transformants carrying the *pmi* gene (phosphomannose isomerase structural gene), has been successfully used.

Kanamycin has been shown to have a dramatic effect on callus formation and proliferation from almond leaves and on adventitious shoot regeneration. Kanamycin sensitivity tests performed on untransformed leaf pieces have shown that concentrations above 68 μM induced severe explant necrosis completely inhibiting callus proliferation (Archilletti *et al.*, 1995; Ainsley *et al.*, 2001a). Thirty-four micromolar kanamycin initially allowed some callus formation but the explants gradually turned brown and no buds were regenerated (Miguel and Oliveira, 1999; Ainsley *et al.*, 2001a). On media containing 17 and 26 μM kanamycin, a few buds could be regenerated (less than 15% of regenerating leaves) but these remained small and white and did not develop further (Miguel and Oliveira, 1999). For callus formation, in order to obtain a higher percentage of transformed explants Archilletti *et al.* (1995) found it also important to start selection only after 3 or 6 days (depending on the genotype) on kanamycin-free medium, before transfer to the selective medium with 68 μM . On the other hand, Ainsley *et al.* (2001a) opted to start selection right after co-cultivation but using a lower level of kanamycin (25 μM), which was maintained through the whole regeneration process. Whilst low levels of kanamycin have the potential to give rise to escapes, higher concentrations compromise explant viability to the

extent that even if transformation occurred, cells are unlikely to survive the selection procedure.

In the case where transformed plants were recovered, Miguel and Oliveira (1999) report the application of kanamycin selection pressure immediately after co-cultivation with *Agrobacterium* but with a low concentration (17 or 26 μM), which was maintained during the induction period, but increased to 86 μM in the elongation phase. The surviving shoots were then propagated in selective conditions with 51 μM for two subcultures, and afterwards transferred to kanamycin-free micropropagation medium. In the report of Costa *et al.* (2006), selection was also applied immediately after co-cultivation with 26 μM kanamycin, which was maintained during shoot elongation and only increased in micropropagation, first to 51 μM for two cycles and to 86 μM thereafter (Costa *et al.*, 2006). This latter strategy allowed a 40-fold increase in transformation efficiency (from 0.1% to up to 4%) when compared to the previously reported work of Miguel and Oliveira (1999). Indeed, all shoots surviving five subcultures on micropropagation medium (3 subcultures at 86 μM kanamycin) were confirmed as transformed by Southern blotting (Costa *et al.*, 2006). Moreover, the transgenic shoots resisted an experiment to which they were subject 3 years after having been transformed: they were transferred to medium containing 172, 344, or 516 μM kanamycin, for four subcultures, and were found to resist these high concentrations and even grew axillary buds.

In the work of Ramesh *et al.* (2006), the regeneration of *nptII* PCR-positive transgenic plants was achieved in the absence of selection pressure, which was applied 70 days after co-cultivation with 15 μM kanamycin. According to these authors, initiation of selection 3 days after co-cultivation (with 15 μM kanamycin) completely blocked shoot initiation, and selection applied 21 days after co-cultivation (with 15 or 20 μM kanamycin) resulted in the formation of a small number of buds, which developed into small shoots that remained stunted and did not grow further. The delayed selection strategy allowed the recovery of transgenic shoots with an efficiency of 5.6%, based on PCR screens, and the authors report that six PCR-positive transgenic shoots selected for testing in Southern analyses confirmed transgene integration.

The effect on almond adventitious regeneration from leaves of other negative selection agents, as alternatives to kanamycin, has also been tested on explants subjected to microprojectile bombardment (Miguel, 1998). Hygromycin at 10 or 25 mg l⁻¹ and phosphinothricin at 1 or 2 mg l⁻¹ were tested for selection applied 5 or 21 days after bombardment and revealed extremely deleterious for control explants (nonbombarded leaves) in any test concentration. These, when cultured in the presence of hygromycin or phosphinothricin, regenerated only a few adventitious shoots if the selective agent was applied 3 weeks after culture initiation, but severe browning of shoots and eventual necrosis occurred within 3–4 weeks. Bombarded control leaves not subjected to selective pressure showed a regeneration rate of 57%, which is already within the range documented for untransformed leaves (Miguel, 1998).

Recently, Ramesh *et al.* (2006) have reported the use of a positive selection strategy based on the inhibition of growth of nontransformed tissue through carbohydrate starvation. The phosphomannose isomerase structural gene (*pmi*) has been used as selection marker. This gene gives the ability to transgenic tissues to survive by utilizing mannose as a carbohydrate source that would otherwise accumulate in plant cells as mannose-6-phosphate blocking glycolysis and preventing further growth (Goldsworthy and Street, 1965). In tissue culture, almond can readily utilize sucrose, fructose, or glucose as carbon source but grows poorly on mannose, making the mannose/PMI (phosphomannose isomerase) selection protocol an attractive selection option. At 20 g l⁻¹ mannose, no callus formation was observed from almond leaf explants but mannose concentrations above 2.5 g l⁻¹ severely impacted callus growth and shoot regeneration (Ramesh *et al.*, 2006). The authors reported the regeneration of transgenic shoots from the cultivar Ne Plus Ultra on medium containing 2.5 g l⁻¹ mannose together with 15 g l⁻¹ sucrose but selection pressure was initiated 21 days after transformation.

2.4 Regeneration of Whole Plant

One of the prerequisites for successful plant transformation, the ability to induce adventitious

shoot regeneration, has been demonstrated in almond from juvenile tissues (Mehra and Mehra, 1974; Seirlis *et al.*, 1979; Bimal and Jha, 1985; Rugini, 1986; Miguel, 1998; Ainsley *et al.*, 2001b) and from adult tissues (Miguel *et al.*, 1996; Ainsley *et al.*, 2000). Regeneration efficiencies are usually low, particularly when working with mature explants. Because biotechnology will ultimately allow the discrete modification of existing elite cultivars in one or more traits, regeneration pathways involving explants of mature tree origin are of major importance. However, the difficulties found in almond regeneration have limited the use of genetic transformation strategies for the improvement of cultivars of this species. Up to now, regeneration of whole plants from transformed almond tissues has been reported from leaf explants of both juvenile and adult material through adventitious shoot organogenesis (Miguel and Oliveira, 1999; Costa *et al.*, 2006; Ramesh *et al.*, 2006).

The infection and co-cultivation of almond leaf explants with *Agrobacterium*, as compared to the control leaves (untransformed leaves induced on cefotaxime-containing medium) has lowered the efficiency of adventitious shoot regeneration, in which average regeneration rates of 75% were observed (Miguel, 1998). There was a general decrease in regeneration capacity after co-cultivation even in the absence of selective agent.

The use of a preculture period of leaves for 3 days on shoot induction medium before wounding and *Agrobacterium* infection was reported as resulting in higher regeneration rates and leading to almost a sevenfold increase in the percentage of GUS positive explants. The effect on transformation efficiency of explant preculture prior to infection with *Agrobacterium* is not very clear. It has been reported that extended preculture may be deleterious for transformation in some species such as apple and kiwifruit (Janssen and Gardner, 1993; De Bondt *et al.*, 1994). In other cases, the preculture period may be considered important for tissue recovery and cell division induction after the stress imposed by wounding. In almond, preculture is usually applied before further wounding the excised leaves, therefore factors other than tissue recovery after wounding stress may be involved. It is possible that the previous exposure of leaf cells to a hormone-containing shoot induction medium brings them to a receptive

state, so that when wounding is performed cell division starts more rapidly. Since T-DNA integration occurs when cells are dividing, the higher number of GUS-expressing units when preculture is applied could be explained by the existence of more cells in active division during the co-cultivation period, and therefore a higher number of receptive cells.

Ramesh *et al.* (2006) also report on the use of a leaf preculture period of 3 days in liquid medium prior to wounding and transformation. Nevertheless, and in spite of the several improvements introduced in the available transformation protocols, the rate of transgenic plant recovery is still limiting.

From the study of the distribution of GUS-expressing cells and observation of leaf explants by light microscopy and scanning electron microscopy following co-cultivation with *Agrobacterium*, it is clear that neither *Agrobacterium* interaction nor T-DNA transfer appear to be the limiting step in transgenic almond recovery. Bacteria have access to all cell types within the explant (Figure 1e) and therefore, accessibility of the transformation vector to the regeneration-competent cells, should not impose constraints on transformation. Extensive bacterial proliferation was observed in the intercellular spaces near the wounds (Figure 1e, detail in bottom insert) and surrounding the dividing cells. A second early step in infection is the attachment of bacteria to the target plant cell, possibly through specific recognition sites. Fibrils that are produced by *Agrobacterium* for attachment to the plant cell wall were also observed (Figure 1d), but were much more frequent in leaves co-cultivated with EHA105 strain than with LBA4404 (Miguel, 1998).

In spite of the readily access of bacteria to all cell types within the almond leaf explants, mainly in wound surrounding areas, it is known from studies in other plant species that not all cell types show susceptibility to *Agrobacterium* infection. Precise localization at the microscopic level of the cells showing expression of the *gusA* transgene also was therefore attempted. Most GUS-expressing cells were found in the mesophyll, in several cell layers between the adaxial and abaxial epidermis, and also in the vascular tissues (Figure 1f). The great majority of these cells were located in the proximity of wounded tissues.

The investigation of the cellular origins and timing of events leading to shoot induction from leaf explants (Miguel, 1998) suggested that shoots had a multicellular origin and revealed vascular connections between the adventitious shoots and the vascular bundles of the original explant (Figure 1g, h). Both these situations are detrimental to the development of transformed shoots. Although nutrient supply from the main body of the explant is essential for the developing shoots, the effects of antibiotic selection on the untransformed explant tissues can be extremely detrimental to the transformed shoots. The problems underlying the difficulties in regenerating transgenic almond plants are probably more related to the shoot regeneration pattern than to the transformation efficiency. To overcome this recalcitrance, alternative regeneration systems based on different developmental patterns should be investigated. In other species such as *Linum*, *Vitis*, and *Dendranthema*, it has been reported that recalcitrance to transgenic shoot regeneration may result from differential competence of cells for transformation and regeneration (Jordan and McHughen, 1988; Colby *et al.*, 1991; Lowe *et al.*, 1993). In *Kohleria*, where a highly efficient regeneration system is available, transgenic plant recovery is inefficient because shoot regeneration occurs from a particular epidermal cell type, which proved hardly susceptible to *Agrobacterium* infection (Geier and Sangwan, 1996).

The regeneration patterns from different types of explants, such as roots and internodes, should be investigated. Adventitious shoots (Mehra and Mehra, 1974; Seirlis *et al.*, 1979; Bimal and Jha, 1985; Rugini, 1986; Miguel, 1998; Ainsley *et al.*, 2000) and structures resembling somatic embryos (Miguel, 1998) have been induced from cotyledons. Whilst this approach would not maintain clonal integrity, efficient regeneration from immature almond explants could provide information to improve the protocols used for regenerating adult tissues. Costa *et al.* (2006) have tested the effect of having 150 μ M AS in the induction medium used for adventitious regeneration from almond leaves. When using the modified selection scheme, these authors obtained a threefold increase in transformation efficiency (from slightly less than 4% to over 12%). It had been previously reported that this compound added to the plant culture medium

promoted organized growth that otherwise did not occur, in the aromatic plant *Levisticum officinale* transformed with *A. rhizogenes* (Santos *et al.*, 2005). Costa *et al.* (2006) suggest that prolonged leaf explant exposure to AS may have induced a favorable stress response leading to improved regeneration ability, besides its well-known effect as inducer of *Agrobacterium* virulence during co-cultivation. In such work, the presence of AS together with the use of a different selection strategy allowed to increase the transformation efficiency from 0.1% (Miguel and Oliveira, 1999) to 12.3%. This improvement was even higher considering the regeneration efficiency of control leaves

2.5 Testing of Activity and Stability of Inheritance of the Gene, Adverse Effects on Growth, Yield, and Quality

Almond adventitious roots obtained by *A. rhizogenes*-mediated transfer of *rol* genes, reported by Damiano *et al.* (1995), were found to display the typical plagiotropic emergence, but after transfer to soil they grew vigorously and the plants did not have any special requirements.

The first transgenic almond shoots, regenerated 9 years ago (Miguel and Oliveira, 1999) have in recent analyses proved to maintain the transgenic status. These plants have been maintained *in vitro* in the absence of selection conditions under regular subculture regime (every 2 months) and remained positive as assessed by Southern blot analyses performed in parallel on newly transformed shoots (Costa *et al.*, 2006). This transgenic material was never transferred to soil. However, in the work of Ramesh *et al.* (2006), where transgenic plants were rooted and transferred to soil, the authors report that in a contained glasshouse, and under natural light and temperature conditions over winter, the plants were able to flower in less than 18 months after planting (Ramesh *et al.*, 2006) and produced kernels (Almond Board of Australia, <http://www.aussiealmonds.com>). Ramesh *et al.* (2006) suggest that this fast flowering may be due to the *in vitro* culture that led to a reduction in the vegetative phase common to almond plants raised from seeds. However, if adult (cultivar) material was used in the transformation/regeneration experiments, this precocity might be suspected. No

data are yet available regarding negative effects on growth, yield, or quality of this material.

3. FUTURE ROAD MAP

3.1 Expected Products

One of the main expectations from almond genetic engineering is breaking down SI in specific cultivars by silencing the S-RNase genes, either by antisense technology or RNA interference. This is especially important when specific cultivars are identified as important producers, as it is the case of “Nonpareil” in California. This goal appears now attainable since the S-RNase gene sequences of various alleles are already obtained and since a transformation protocol for a cultivar (“Ne Plus Ultra”) is available since 2006 (see point 2.1, Table 1). From transformation experiments with “Nonpareil”, however, it was still only possible to regenerate transgenic callus (Ainsley *et al.*, 2001a).

Also important to obtain but still hard to reach through genetic engineering is late blooming. The complex system controlling flowering time still did not reveal a key gene sequence able to delay flowering in almond. However, from molecular studies conducted to identify genes involved in almond flowering, there is a candidate gene, *PrpFAR1*, that may be interesting to study further. This gene shares 52% homology to *far-red-impaired responsive protein gene* of *Arabidopsis thaliana*, and co-segregated (Silva *et al.*, 2005, 2007) with a QTL for late blooming identified by Dirlewanger *et al.* (1999) that mapped in the linkage group 7.

Diseases are potentially another target for transgenic breeding, especially when no control methods are available as it happens for viral diseases. Constructs aiming to block the proliferation of PDV were prepared carrying the original or modified PDV coat protein gene sequences (in sense or antisense orientation, mutated or without start codon), aiming to understand the mechanisms underlying PDV replication in host cells and to identify the most appropriate construct for almond transformation. The constructs prepared were constitutively expressed in *N. benthamiana* (an easy-to-transform model plant susceptible to PDV) and the transgenic plant behavior was studied in progenies upon controlled infection

using a different PDV strain (Raquel, 2005). After extensive molecular characterization and controlled infections performed on transformants and their progenies, PDV resistance achieved by the coat protein messenger RNA (mRNA) was observed in plants infected by a PDV isolate sharing only 91% homology with the isolate used for cpPDV cloning. When coat protein was expressed, resistance was only achieved if the construct was mutated in the active site responsible for activation of virus replication. This result points at a major role of the mutated sequence in the virus for its ability to replicate and proliferate. This work (Raquel *et al.*, 2008) demonstrates that PDV resistance can be achieved in plants expressing the PDV coat protein sequences, and provides a good clue of which construct could be the best for controlling PDV in almond orchards.

From other experiments, a number of genes isolated from almond could be selected for homologous and heterologous transformation assays for gene function assessment. It is the case, for instance, of genes putatively involved in adventitious regeneration, such as the almond homolog of *knotted-1*, named *PdKn1* (for *Prunus dulcis Knotted1-like* homeobox gene), and a number of genes identified from hybridization of two cDNA suppression subtractive libraries (SSH) and microarray analyses. The two libraries were prepared for two time frames of the adventitious regeneration process (the early stage of shoot induction, days 1–8, and the late stage, days 9–20) and some differentially expressed genes were selected for expression analyses by real-time quantitative PCR (Santos *et al.*, 2007).

3.2 Addressing Risks and Concerns

Like any other breeding strategy, transgenesis may yield high quality and high yielding varieties that may tend to disrupt traditional production schemes and replace older/worse performing cultivars. This, however, is not a new event in agriculture and, like other breeding systems, both the governments and the private sector should endeavor to protect farmers'/breeders' rights and also to preserve, for future generations and for a rapidly changing global climate, the existing germplasm diversity. In some countries (as in Portugal), new almond orchards are no

longer established using local varieties, but instead are established using improved higher yielding cultivars obtained from abroad, with obvious impact on the erosion of local genetic diversity, sometimes cultivars with higher nut quality.

Hardly, will any transformation event leading to a better producing almond plant, such as self-fertility, late blooming, or virus resistance through coat protein gene sequences, have any harmful effect in human health. However, as with other transgenic plant products, appropriate quality analyses should be performed to identify potential negative effects, eventually also including postmarket surveillance (Batista *et al.*, 2005).

A putative impact on the environment has been anticipated in the case of engineering viral resistance through coat protein gene sequences. The wardens of this vision argue that the transgene sequences may find ways to recombine with other viruses (Frischmuth and Stanley, 1998) leading to potentially new and particularly virulent viral forms. However, there is no scientific reason to suppose that the putative viral recombination will differ for transgenic and nontransgenic plants infected with two viruses, unless, for instance, viral recombination frequency is increased in transgenics. The transgenic plant carrying a virus-derived sequence presents an increase in risk compared to the nontransgenic plant only if the frequency with which viable recombinants are generated in transgenic is significantly higher.

However, any field releases of transgenic virus-resistant material should be monitored regarding potential environmental impacts.

3.3 Expected Technologies

The production of transgenic plants relies upon the selection and recovery of transformed cells. The use of either antibiotic or herbicide tolerance/R genes as selectable markers may raise concerns regarding safety and environmental impacts. The use of positive selection protocols such as the use of mannose/*pmi* selection reported for almond (Ramesh *et al.*, 2006) may circumvent these problems, although it may still be desirable to have an efficient system to remove selectable marker genes. This would allow retransforming transgenic plants using the same original marker and thereby repeatedly pyramid a number of

transgenes as more traits have to be incorporated into a transgenic crop. For removal of marker genes, several methods, such as co-transformation, transposition or site-specific recombination, have been successfully employed (for reviews, see Hare and Chua, 2002; Scutt *et al.*, 2002). The multiautotransformation (MAT) vector system represents a highly sophisticated approach for the removal of nuclear marker genes (Ebinuma *et al.*, 1997), in which a chosen trait transgene is placed adjacent to a multigenic element flanked by recombination sites. The obvious disadvantage of these strategies is the need for repeated and time-consuming transformation cycles, and the increased chances of somaclonal variation.

In association with these technologies, the precise control of the integration site could be important for optimizing the transformation technology, although much higher transformation efficiency would be required.

3.4 Intellectual Property Rights (IPR) and Public Perceptions

The use of transgenic breeding for almond improvement does not seem economically viable except for specific cases in which elite cultivars of vast utilization are targeted (as it could be the case for “Nonpareil”). This situation is due to the fact that most biotechnologies are patented and those that are no longer under the scope of the patents are conveniently regarded as old fashioned and potentially harmful to health or environment (such as the use of selectable markers for antibiotic resistance/tolerance). Patents not only have the role of rewarding innovation and encouraging the private sector to invest, but also are frequently viewed as necessary for attracting venture capital in a start up biotech company. However, transactions involving IPR are very expensive, and this makes it quite inevitable since at present transgenic breeding can only be handled by companies large enough, and prepared enough, to deal with, and handle, IPR processes. Small/starting companies are simply discouraged by the need to negotiate existing patent claims on important technologies.

Additionally, conflicts with farmers who prefer to use nontransgenic plants can be particularly hard for a plant with high SI such as almond that

requires cross-pollination (and pollinating bees) and from which the edible part is the fertilization-derived kernel. The kernel will thus contain the genes brought from the pollen-donor tree.

Regarding human health, environmental impacts and public perception, clearly the introduction of self-fertility would be less controversial than coat protein-mediated virus resistance. Moreover, the damage by Ilarviruses in almond is not comparable to damages by plum pox virus in other *Prunoideae* that makes it harder to defend the need for engineering virus resistance in almond.

Still, genetic engineering tools for almond are important and should be available for future needs, including for gene functional studies.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the colleagues Rafael Socías i Company, Ossama Kodad (Zaragoza), Federico Dicenta, Pedro Martínez-Gómez (Murcia), and Pere Arús (Cabrils) for providing information from manuscripts still in press or in preparation.

Persian Walnut

Monica T. Britton¹, Charles A. Leslie¹, Emilia Caboni², Abhaya M. Dandekar¹
and Gale H. McGranahan¹

¹Department of Plant Sciences, University of California, Davis, CA, USA, ²Istituto Sperimentale Frutticoltura, Rome, Italy

1. INTRODUCTION

1.1 History, Origin, and Distribution

The Persian walnut (*Juglans regia* L.) is the horticulturally most developed and widely cultivated of all walnut species. It is mentioned in the Bible and was used for food and medicine in Greek and Roman times, and likely had even earlier horticultural origins in China. Millennia of trade, transport, and commerce have contributed to widespread naturalization of cultivated trees, greatly extending the original range, which is believed to encompass the lower altitudes of the mountainous regions of central Asia. Although “Persian” better describes the native range of this walnut species, its most common name in the United States is “English” walnut, apparently because nuts were originally shipped there in English ships.

J. regia is native to central Asia, where it grows as a wild or semicultivated tree in a wide area from southeastern Europe and the Caucasus to Turkey and Iran, through southern portions of the former Soviet Union into China and the eastern Himalayas. It has been cultivated for its nuts for at least several thousand years and was likely introduced into European commerce and agriculture by the ancient Greeks. It was prized by the Romans as *Jovis Glans* (“Jupiter’s nut”) and was utilized in medieval Europe as an herbal

medicine, particularly for brain and scalp ailments. Since its introduction into North America it has commonly been referred to as the English walnut to distinguish it from the American black walnut (Leslie and McGranahan, 1998).

1.2 Botanical Description

There are approximately 20 species of walnut worldwide, many of which are valued for their nut production and timber quality. *J. regia*, the Persian walnut, is the primary species used in commercial walnut production. It is currently cultivated in many temperate regions including much of the Mediterranean, central Asia, northern India, China, South Africa, Argentina, Chile, and Australia. In the United States, this crop is produced almost entirely in California, where scion cultivars are grafted onto rootstock of either the native California black walnut (*Juglans hindsii*) or *J. hindsii* × *J. regia* hybrids known as Paradox.

1.2.1 Taxonomy

The family Juglandaceae includes about 60 species of deciduous, monoecious trees or shrubs with alternate, pinnately compound leaves. The genus *Juglans* consists of four sections. Three of these, *Rhysocaryon* (black walnuts native to the North

America), *Cardiocaryon* (Japanese, Manchurian and Chinese walnuts, including selections known as heartnuts), and *Trachycaryon* (the butternut of eastern North America), exhibit thick shells and nondehiscent hulls. The fourth section, *Juglans*, is comprised of a single species, *J. regia* L., distinguished by a dehiscent hull, which separates from the shell at maturity (Manning, 1978).

1.2.2 Habit

Persian walnut trees are typically over 30 m tall, with a broad canopy of compound pinnate leaves (Prasad, 2003). The first branches are formed 2 to 4 years after germination, after which hierarchical branching continues from the main stem. Initial flowering is seen in 3- to 9-year-old trees. An unusual type in Asia flowers in the first year. After flowering begins, the main stem becomes forked and canopy architecture develops (Sabatier and Barthélémy, 2001).

There is a high degree of morphological variability among *J. regia* cultivars. Some bear their flowers (and thus, nuts) from terminal buds, while others bear on axial buds. Mid to late leafing and lateral fruit-bearing offspring populations predominate in California varieties and tend to be more precocious and have a higher yield earlier than those that bear their nuts terminally (McGranahan and Leslie, 1990).

J. regia trees are monoecious with male flowers borne in catkins and female flowers in pistillate spikes of mostly two, but sometimes as many as five, flowers at the tips of terminal or lateral shoots. Flowering is dichogamous with either the male (protandry) or female (protogyny) flowers maturing first. Pollen is wind borne and the dichogamy promotes outcrossing (Forde and Griggs, 1972). The walnut fruit is an ovoid drupe with an external fleshy pulp surrounding the nut. After ripening, the fruit dehisces and releases the nut, which is composed of a highly lignified shell surrounding the seed (Cannella and Dernini, 2006).

1.2.3 Habitat

In their native habitat, walnuts are most commonly found among the foothills and at temperate elevations, where they grow on disturbed forest

sites or on well-drained river bottom soils with a variety of coniferous and broad-leaved forest species. They are a component of wild fruit forests that include wild apricot, pear, almond, myrobalan plum, and grape. Most varieties of walnut require 600–1200 chilling hours (below 7 °C) for nut production. Cultivated walnuts do best in the Mediterranean climate in deep, well-drained, nonstratified soils (Ramos, 1998). In Europe, commercially cultivated trees can still be found in small orchards, but establishment of large orchards is now more common, similar to the practice in California.

1.3 Economic Importance

Worldwide, over 1.5 million metric tons of walnuts are produced annually valued at over \$2 billion. The top 10 walnut-producing countries are detailed in Table 1. Yield per hectare can be as high as 6 t with new cultivars, although a good yield is 2–3 t. Major walnut-producing regions of the world are China with 420 000 t, the United States with 322 000 t, and Europe with about 260 000 t. Within the United States, 100% of Persian walnut (*J. regia*) production occurs on over 95 000 ha in California, where it is one of the top 20 agricultural commodities, with an annual production value of more than \$500 million (California Department of Food and Agriculture, 2006; United States Department of Agriculture, 2006).

1.3.1 Utilities

While Persian walnuts are primarily a food crop, the timber is also greatly prized, particularly in Europe, where it is considered to be the most valuable wood for furniture manufacture. Harvesting of walnut wood has depleted some of the forests in its native range. In addition, shells are used as an abrasive in diverse applications including metal polishing and oil drilling.

1.3.2 Nutritional and/or other economic attributes

Walnuts are very high in nutritional content, containing 14–24% protein and 52–70% fat. Almost all of the oil is in the form of

Table 1 Leading walnut-producing countries in 2005^(a)

Country	Rank	Production (t)	Percentage of world production	Area harvested (ha)	Yield (t ha ⁻¹)
China	1	420 000	27.76	186 000	2.26
United States	2	322 050	21.29	95 000	3.39
Iran	3	150 000	9.92	65 000	2.31
Turkey	4	133 000	8.79	70 000	1.90
Ukraine	5	93 000	6.15	14 000	6.64
France	6	33 241	2.20	16 238	2.05
India	7	31 500	2.08	30 800	1.02

Serbia and Montenegro	9	24 000	1.59	13 200	1.82
Spain	10	22 000	1.45	7 500	2.93
All others		257 791	16.99	132 987	1.93
Total		1 512 816	100.00	635 725	2.38

^(a) Source: FAOSTAT, Agricultural production data, crops primary, walnut

polyunsaturated fats, including α -linoleic acid. Among the protein constituents is the essential amino acid taurine, which is generally lacking in vegetarian diets. Walnuts also contain several nutritionally important vitamins and minerals, including vitamins A and E, niacin, riboflavin, thiamin, magnesium, phosphorus, and potassium (Prasad, 2003). Vitamin E is an antioxidant that may provide some protection against walnut rancidity. Phytosterols may lower serum cholesterol in consumers due to their ability to inhibit absorption in the intestine (Savage *et al.*, 2001).

Phenolic compounds are responsible for the slightly astringent flavor of walnuts. The pellicle, a thin skin surrounding the kernel, is rich in these antioxidant compounds, which naturally help protect the kernel against rancidity brought on by oxidation of fatty acids (Colaric *et al.*, 2005). When ingested, polyphenolics may inhibit oxidation of low-density lipoproteins, as indicated by the reduced incidence of cardiovascular disease in certain studies (Anderson *et al.*, 2001).

Over the past several years, a large body of evidence has accumulated from studies that point to health benefits derived from incorporating walnuts into a healthy diet. Diseases that appear to benefit from walnut consumption include cardiovascular and coronary heart disease (Zambon *et al.*, 2000; Morgan *et al.*, 2002; Zibaenezhad *et al.*, 2003; Ros *et al.*, 2004; Reiter *et al.*, 2005), type 2 diabetes (Fukuda *et al.*, 2004; Gillen *et al.*, 2005), Alzheimer's disease (Chauhan *et al.*, 2004), liver cytotoxicity (An *et al.*, 2005), tooth decay (Jagtap and Karkera, 2000), and acne

(Qadan *et al.*, 2005). Studies on the effects of walnuts and coronary heart disease have been reviewed by Feldman (2002). There is also evidence that compounds contained in walnut may be useful in reducing the toxicity of broad-spectrum chemotherapy drugs (Haque *et al.*, 2003).

The beneficial aspects of walnuts are derived from both their unique fatty acid composition and numerous products of secondary metabolism, including high levels of fiber, folate, polyphenolic compounds, tannins, and the amino acid arginine (Ros *et al.*, 2004). Although walnuts are high in total fat content, increased consumption of walnuts does not result in gains to body weight, because the resulting diet has a low proportion of saturated fat (Zambon *et al.*, 2000; Gillen *et al.*, 2005).

1.3.3 Industrial uses

Powdered walnut shells are used in abrasives, by the plastics industry for fillers, and by the oil industry in drilling mud. By-products of walnuts are also used as dyes, and in the processing of leather (tannins). Walnut oil is used in artists' paints, due to its fast drying time (Prasad, 2003).

1.4 Traditional Breeding

As is true for many seeded plants, the history of walnut breeding began through chance selection of superior nuts and seedlings. Walnuts have traditionally been grown from seed in most

parts of the world, but have been more recently been propagated by grafting. In California, a formal breeding program was initiated at the University of California at Davis in 1948 under the direction of Gene Serr and Harold Forde. After Gene Serr retired in 1965, the breeding program was continued under Harold Forde until 1978. This was a very successful partnership that resulted in the release of 15 cultivars (Serr and Forde, 1968; McGranahan *et al.*, 1990b; McGranahan *et al.*, 1992; Tulecke and McGranahan, 1994). The breeding program at UC Davis is ongoing with major breeding objectives to increase yield, quality, and range of harvest dates, while decreasing the amount of chemical input required to control pests and diseases. For a recent review of *J. regia* breeding and genetics, see Dandekar *et al.* (2005).

In Europe, older varieties are generally well adapted to local climatic conditions, but often lack important agronomic traits (Germain, 1992). For this reason, during the last 20 years significant work involving seedling selection has been carried out using local populations of *J. regia* throughout Europe. Selection of progeny from natural populations is critical to create, through hybridization, new cultivars with combinations of multiple valuable traits. Additionally, a goal of European selection and breeding is to separate the production of wood from the production of fruit, with some breeding programs designed to increase the production of high-quality wood and with particular attention to characters such as vigor, number of branches, and stem forms (Jay-Allemand *et al.*, 1996; Casal *et al.*, 2006; Fernández-López *et al.*, 2006; Hemery and Russell, 2006).

1.4.1 Rootstocks

Nearly all walnut production in the United States, and increasingly worldwide, is derived from grafted scion varieties on seedling rootstocks. This reflects the difficulty of rooting walnut cuttings, which precluded, until recently, substantial use of either rooted scions or improved clonal rootstocks. Employment of rootstocks is driven by the need to deal with soil, environment, disease, and pest problems (McGranahan and Catlin, 1987). In California, *J. hindsii* (Northern California black walnut) was preferred for much of the first half of

the 20th century as it is a native species adapted to several soil-related problems, including resistance to crown and root rot caused by *Armillaria mellea* (oak root fungus) and tolerance to water logging and drought (Smith *et al.*, 1912). Today, the most popular rootstocks are the interspecific hybrids, primarily “Paradox”, a hybrid between *J. hindsii* and *J. regia* described in 1893 by Burbank (Whitson *et al.*, 1914; Howard, 1945). However, because these hybrids are male sterile, traditional breeding between Paradox selections cannot be accomplished. However, crosses can be made using Paradox as the female parent.

The major objective for walnut rootstock breeding is vigor, in order to promote rapid growth of the scion under a variety of soil and environmental conditions and to establish rapidly a full-sized bearing canopy. Other objectives include resistance to diseases and pests, most notably *Phytophthora*, nematodes, and crown gall, as well as tolerance to cherry leafroll virus and tolerance of soil-related problems, including water logging and salt accumulation. There is interest in controlling tree size, but not at the cost of vigor.

1.4.2 Scions

The ideal walnut cultivar would be relatively late leafing to escape the rains that spread walnut blight (*Xanthomonas campestris* pv. *juglandis*), precocious (yielding more than 500 kg ha⁻¹ in the fourth year) and vegetatively vigorous with bearing on both terminal and lateral shoots. It would have a low incidence of pistillate flower abscission and fruit drop and would not be alternate bearing. It would have high production capacity with low chemical input required. The harvest season would end in early October. The nutshell would be relatively smooth, well sealed, and make up no more than the 50% of the nut weight. The nuts would fit the category of large or jumbo. The kernel would be plump and light colored, weighing about 7–8 g, and would be extracted easily in halves. The tree would be resistant to pests and diseases.

1.4.3 Tools and strategies

Traditional breeding activities incorporate the collection and evaluation of germplasm, controlled crosses, open-pollination between advanced

selections, evaluation of progeny, selection and field trials prior to release. The University of California walnut germplasm collection and the National Clonal Germplasm Repository walnut collection are both housed at UC Davis, and contain plants collected from the native Asian ranges of *Juglans*. This allows the introduction of genetic variation and desirable traits by crossing plants from the germplasm collections with existing elite cultivars (McGranahan and Leslie, 2006).

Clonal propagation of rootstocks is beginning to be commercialized in California and Europe. To evaluate the genetic diversity of commercially available Paradox rootstocks, a study was initiated in 1996. Evaluations included screens for resistance to root lesion nematode (*Pratylenchus vulnus*), crown gall, and *Phytophthora*. Some selections were found with tolerance to individual pathogens and are currently being micropropagated (McGranahan and Leslie, 2006).

Molecular markers can be used for traditional genetic and breeding strategies, including selection of desired progeny, linkage mapping, and map-based cloning. Mapping efforts in Persian walnuts have utilized random amplified polymorphic DNA (RAPD), amplified fragment length polymorphism (AFLP), and microsatellite markers (Aradhya *et al.*, 2001; Malvolti *et al.*, 2001). In Turkey, most *J. regia* are grown from seedlings, rather than grafted, representing an extensive germplasm. Some of these genotypes have been characterized using AFLP and SAMPL techniques (Kafkas *et al.*, 2005). Simple sequence repeat (SSR), intersimple sequence repeat (ISSR), and RAPD markers have also been used to characterize *J. regia* cultivars and to discriminate between intra- and interspecific hybrids and to estimate genetic diversity (Abuin *et al.*, 2002; Potter *et al.*, 2002a; Dangl *et al.*, 2005; Abuin *et al.*, 2006; Foroni *et al.*, 2006; Pollegioni *et al.*, 2006).

Isozyme markers have been used to identify the inheritance of important enzyme systems, including 6-phosphogluconate dehydrogenase, shikimate dehydrogenase, malate dehydrogenase, and phosphoglucomutase (Aleta *et al.*, 1993). The use of phenols as genetic markers in walnut has also been proposed to identify cultivars and to screen the progeny of interspecific crosses (Jay-Allemand *et al.*, 2001).

Although the term “Paradox” generally designates rootstock hybrids between *J. hindsii* and

J. regia, it can be applied to any hybrid between a species of black walnut and *J. regia*. In commercial nurseries, the trees are open pollinated and so the genotypes of the seedling progeny are unknown. A 1996 study used the ribosomal DNA intertranscribed (ITS) regions and noncoding spacer regions from the chloroplast genome to identify unique sequence markers for each species to develop molecular markers that now allow the parentage of individual Paradox seedlings to be determined. It was shown that several other black walnut species and their hybrids were used to produce Paradox seedlings (Potter *et al.*, 2002b).

Chloroplast and mitochondrial polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) genetic markers have also been used to compare European and Asiatic genotypes of *J. regia*. The amount of diversity found between these genotypes has been used to support the hypothesis that some *J. regia* populations survived in Europe during the last glaciation. This hypothesis is in contrast to the generally held belief that *J. regia* became extinct in Europe during glacial periods, and was reintroduced from Asian populations after the climate had warmed (Fornari *et al.*, 2001).

1.5 Limitations of Conventional Breeding

Breeding and selection are actively used to improve scion cultivars. However, controlled pollinations are very labor intensive and produce relatively few seedlings per cross. Open pollination is also performed by blowing pollen from selected male parents into isolated orchards of the desired female parent. This is less labor intensive and produces thousands of seedlings (McGranahan and Leslie, 2006). But, because all walnut cultivars are very heterozygous in their genetic makeup, many years of evaluation are required before individual selections can be released. Therefore, to shorten the lengthy process, the use of techniques including embryo rescue and genetic transformation, combined with micropropagation, can provide the means to incorporate desired traits in existing elite cultivars and to pyramid disease and pest resistance in rootstocks.

Backcross breeding is currently being used to develop a rootstock that would incorporate the *J. regia* response to cherry leafroll virus (CLRV)

with the vigor of Paradox. To accomplish this, individual vigorous and tolerant seedlings are chosen from a backcross generation (*J. hindsii* × *J. regia*) × *J. regia*. However, this process takes many years and requires a great deal of resources to accomplish due to the long generation time of the trees: it has taken 17 years from the initial planting of 13 000 Paradox offspring seedlings through the selection process and clonal propagation to reach the stage where grower trials can begin (McGranahan and Leslie, 2006).

Phytophthora is the most significant root disease of walnut in California, and is easily spread by irrigation water and periodic winter flooding (Mircetich and Matheron, 1983). While it is possible to find individual healthy rootstocks in orchards decimated by this pathogen, it is very difficult to capture this potential resistance due to the variability in disease symptoms and the possibility of disease escapes. The difficulty in propagating such chance trees to conduct further testing and for subsequent commercialization is also a hindrance.

Wingnut (genus *Pterocarya*) is very resistant to *Phytophthora*, but when used as a rootstock it is graft incompatible with some cultivars of *J. regia*. Hybrids between walnut and wingnut could potentially be used as long as they are compatible and retain the resistant trait, but hybrids developed through controlled pollination and embryo rescue did not survive over the winter in the field (McGranahan *et al.*, 1986).

CLRV is the major viral disease of walnuts, and is found in California as well as in France, Italy, Hungary, and the United Kingdom. It is spread by pollen (Massalski and Cooper, 1984) and is systemic and virtually asymptomatic in *J. regia*. Most black and Paradox rootstocks are resistant to CLRV and prevent systemic spread by a hypersensitive response that is manifested as a black line at the graft union (Mircetich and Rowhani, 1984), which causes a lethal girdle resulting in the decline, dieback, and death of the scion (Mircetich *et al.*, 1980).

1.6 Micropropagation

Walnuts have traditionally been propagated by grafting onto seedling rootstock. Micropropagation has been investigated for propagation of

cultivars on their own roots, for production of selected rootstock clones, and for development of genetically engineered plants. Each walnut species and cultivar generally requires new optimization for successful tissue culture. Commercially, walnuts are micropropagated in only one lab in Spain (López, 2001) and one laboratory in California.

The first reports of micropropagation of Persian walnut are from the early 1980s (Chalupa, 1981; Somers *et al.*, 1982; Rodriguez, 1982a, 1982bb; Caruso, 1983; Cossio and Minolta, 1983; Driver and Kuniyuki, 1984). These techniques have been reviewed (McGranahan *et al.*, 1987; Preece *et al.*, 1989; Leslie and McGranahan, 1992). Micropropagation of mature cultivars (McGranahan *et al.*, 1988a) and better techniques for rooting and acclimatization (Jay-Allemand *et al.*, 1992; Ripetti *et al.*, 1994; Navatel and Bourrain, 2001; Vahdati *et al.*, 2004) have been described more recently.

Driver Kuniyuki walnut (DKW) medium (Driver and Kuniyuki, 1984) was developed specifically for walnut, but success has also been obtained on MS medium (Murashige and Skoog, 1962). A comparison of different media for *J. regia* conducted by Saadat and Hennerty (2002) found that DKW was optimal when 2.2 g l⁻¹ Phytigel was used as the gelling agent.

Walnuts are initiated into culture by introducing disinfested nodal segments of vigorous field or greenhouse-grown shoots. Multiplication occurs through axillary shoot proliferation. Rapid transfer (2–5 times per week) is essential after introduction into culture until discoloration of the medium is no longer evident. Once established, cultures need relatively frequent transfer (2 times per month) for optimum growth (Leslie *et al.*, 2006a).

Techniques for rooting are still under investigation and rooting ability is clone specific. The most promising rooting technique utilizes a two-phase system originally developed by Jay-Allemand *et al.* (1992) and subsequently modified by Navatel and Bourrain (2001) and Vahdati *et al.* (2004). Roots are induced by placing shoots on MS medium containing auxin and at least 40 g l⁻¹ sucrose for 6–8 days in the dark. Induced shoots are then transferred to a root development medium consisting of a mix of one-quarter strength basal DKW medium and vermiculite (to improve aeration) and maintained in the light for 3–4 weeks until roots are

visible. An alternate method is to treat unrooted microshoots with auxin, and root them in vermiculite in a fog chamber (Leslie *et al.*, 2006a). This technique results in a lower percentage of rooted shoots. However, those shoots that do root using this procedure have very little callus and produce roots that are more fibrous than microshoots rooted *in vitro* and show improved survival during acclimatization to greenhouse conditions. Recently, it has been demonstrated that the addition of 1 mM phloroglucinol to the multiplication media increases subsequent rooting (Leslie *et al.*, 2006a).

Rooted shoots are planted in a well-drained potting soil and are acclimated by growth in a fog chamber for 2 weeks followed by a week or two on a shaded greenhouse bench. However, the stress of acclimatization can lead to arrest of the apical meristem. Budbreak can be improved by application of 25 ml l⁻¹ Promalin® (a commercial product containing 1.8% gibberellic acid (a mixture of GA4 and GA7) and 1.8% benzylaminopurine (BAP, Valent Biosciences, Walnut Creek, CA)) as a foliar spray to stimulate growth (Vahdati *et al.*, 2004).

In a study comparing variations of this protocol on several different walnut cultivars, a correlation was found between the vigor of adult trees and their rooting ability. Although smaller microshoots can be produced more rapidly and more efficiently *in vitro*, longer microshoots appear to acclimatize better in the greenhouse, perhaps due to a greater internal reservoir of carbohydrates and a more lignified stem, which may lead to increased pathogen resistance (Vahdati *et al.*, 2004).

Bisbis *et al.* (2003) also found a link between shoot lignification and root development, concluding that signals from the roots, as well as auxin, enhance lignin formation. The lignin was only found in xylem cells, and was correlated positively with the number of developing roots, beginning immediately after treatment with exogenous auxin (Kevers *et al.*, 2004). This appears to trigger peroxidases that are involved in the process of building cell walls. Peroxidase activity had previously been shown to be a good marker for walnut rooting (Gaspar *et al.*, 1992; Ripetti *et al.*, 1994).

While the above techniques are generally effective, it is often found that media must be optimized for specific cultivars and clones. Recent

studies in which different root formation factors have been investigated include those described by Navatel and Bourrain (2001), Dolcet-Sanjuan *et al.* (2004), Caboni and Damiano (2006), Kaur *et al.* (2006), Leslie *et al.* (2006a), and Sánchez-Zamora *et al.* (2006).

1.7 Somatic Embryogenesis

Development of embryos from asexual tissues has been a very useful tool in genetic improvement, particularly because tissues (i.e., leaf discs, protoplasts) commonly used in other plants have not been successfully regenerated to plants in walnut. Somatic embryogenesis has been used to generate triploids (Tulecke and McGranahan, 1988), intergeneric hybrids (McGranahan *et al.*, 1986), and genetically transformed clones (McGranahan *et al.*, 1988b, 1990a; Dandekar *et al.*, 1989).

The techniques were developed for *J. regia* (Tulecke and McGranahan, 1985) but have been applied to other species (Neuman *et al.*, 1993). Immature cotyledonary explants harvested from developing nuts, cultured on conditioning medium for 2–4 weeks and then placed on basal DKW medium, will develop small white somatic embryos from single cells (Polito *et al.*, 1989) on the explants after 8–16 weeks. These new embryos are repetitively embryogenic and with monthly subculturing cultures can be maintained for years.

For initiation and multiplication, embryos are maintained at room temperature in the dark. In the light, embryos turn green and a certain percentage will germinate. Germination frequency can be increased following desiccation over a saturated salt solution (Zn₂SO₄, NH₄NH₃, or MgCl₂) until the embryos are white, with the consistency of popcorn, but not until they have turned brown. Embryos are then returned to DKW basal medium to germinate. Additional details of methods utilized in walnut embryogenesis are given in the reviews by Tulecke *et al.* (1995) and Preece *et al.* (1995).

Currently, a major challenge is to obtain embryogenesis or organogenesis from maternal tissue. This is important because embryos from zygotic tissue do not allow the exact genotype to be predicted, even if both parents are known, due to the high degree of heterozygosity in walnut.

Therefore, genetic transformants derived from zygotic embryos must be brought into the breeding program to combine desirable traits. Efforts to generate somatic embryos from nonzygotic tissues have been unsuccessful (Aly *et al.*, 1992; Vahdati *et al.*, 2006). Repetitively, embryogenic cultures have been obtained from immature anther tissue, but only from one cultivar ("Chandler"). Recently, a modified protocol allowed a somatic embryo line to be generated from immature anthers of a Paradox hybrid (Burbank) (McGranahan, unpublished). This may provide a source of elite rootstock tissue for genetic transformation.

1.8 Molecular Genetics and Genomics

Gene cloning is an important endeavor because tree crops are likely to possess many genes with unique functions that may not be discovered in other plants. However, little progress has been reported primarily due to the few walnut researchers worldwide and the lack of availability of resources to fund these endeavors. One of the useful sources of information on walnut genes is GenBank (NCBI), the public repository for DNA sequences. Currently, this database has over 18 000 entries for genetic sequences among *Juglans* species.

Genes specific to walnut currently being studied include those involved in tannin, naphthoquinone, unsaturated fatty acid, and flavonoid biosynthesis. Several of the genes involved in the biosynthetic pathway of flavonoids have been identified (Beritogoli *et al.*, 2002). Recently, homologs of two *Arabidopsis* genes controlling floral transition and flower differentiation were cloned from microshoots of early mature (EM) walnuts (Breton *et al.*, 2004). EM walnut trees can flower within 1 year of germination and develop into trees that are smaller, bushier, and more cold-hardy than other *J. regia* genotypes. These traits may be useful in transgenic plants and traditional breeding programs.

A key determinate of walnut kernel quality is the oil content, about 90% of which is polyunsaturated, and of that 25% is the ω -3 fatty acid α -linolenic acid (ALA). The presence of unsaturated fatty acids is an important factor in rancidification of walnuts, in which these acids are oxidized, reducing the shelf life of walnut kernels

(Greve *et al.*, 1992). The ω -3 fatty acids have been shown to play an important role in growth and development, nutrition, and disease prevention. Nutritional studies have demonstrated that walnut consumption can reduce the incidence of coronary heart disease. The genes encoding the various fatty acid desaturases involved in the synthesis of polyunsaturated fatty acids, including *fad 2* and *fad 3*, have been cloned from walnut (Dandekar, unpublished).

Oil biosynthesis in the embryo is a major metabolic pathway and some effort has been directed at functional characterization of two key steps in the biosynthesis of polyunsaturated fatty acids. Transgenic walnut embryos expressing antisense *fad 2* or sense *fad 3* have been developed (Dandekar, unpublished) and some of the lines show alterations in the profile and composition of fatty acids. It is hypothesized that expression of antisense *fad 2* will suppress the interconversion of oleic to linoleic acid, leading to an increase in the accumulation of the monounsaturated oleic acid. The expression of sense *fad 3* is aimed at overexpressing the enzyme involved in the conversion of linoleic acid to the ω -3 fatty acid linolenic acid. These studies will be useful in developing walnut lines with high oleic acid (monounsaturated fatty acid) content for stability and also to develop walnuts with increased ω -3 fatty acids.

Enzymes in the phenylpropanoid pathway from phenylalanine lead to the biosynthesis of a range of natural products including flavonoids. Genes for these enzymes, including the key enzyme chalcone synthase, have been investigated in walnuts. Walnuts expressing antisense chalcone synthase were found to be deficient in the accumulation of flavonoids but, interestingly, these deficient plants showed an increase in adventitious root formation (El Euch *et al.*, 1998). These results contrast with other root initiation studies using walnut cotyledons in which adventitious rooting was observed to occur when the appearance of the lateral root primordia coincided with the expression of chalcone synthase at the same location (Ermel *et al.*, 2000). The genes in the phenylpropanoid and flavonoid pathways were also studied to understand the accumulation of flavanols during heartwood formation in black walnut (Beritogoli *et al.*, 2002). The authors concluded that flavanol synthesis was due to the increased transcriptional activity of genes in

the phenylpropanoid pathway in black walnut sapwood cells that are undergoing the transition to heartwood.

Naphthoquinone metabolism has also been investigated and proteins involved in some of the steps have been identified. Naphthoquinones are important for plant defense and may also be involved in developmental processes (Duroux *et al.*, 1998).

2. WALNUT TRANSGENICS

Tree crops, such as walnut, are highly heterozygous and have very long generation times, which make traditional breeding difficult. A large investment in both time and land is needed to grow seedlings to maturity in order to determine nut quality. It is, therefore, advantageous to be able to introduce specific traits into existing elite cultivars. These traits may come from within the germplasm of the genus or from other organisms. Desirable traits for walnut include disease and pest resistance, as well as nut and timber quality. Herbicide tolerance would allow weeds to be controlled economically in nurseries and young orchards without damage to the trees.

2.1 Development of Transgenic Technology in Walnut

Walnut was one of the first woody plants for which *Agrobacterium*-mediated transformation and regeneration were demonstrated (Dandekar *et al.*, 1988; McGranahan *et al.*, 1988b). Somatic embryos, derived from immature cotyledons, are transformed and secondary embryos originating from single transformed cells proliferate as embryos without developing as callus (McGranahan *et al.*, 1988b; Polito *et al.*, 1989). These secondary embryos can be germinated to obtain transformed plants. Early research demonstrated that genes for selection with the antibiotic kanamycin and scorable marker β -glucuronidase (GUS) could be efficiently used to screen transformants (Dandekar *et al.*, 1989; McGranahan *et al.*, 1990a). Green fluorescent protein (GFP) has also been successfully used as a scorable marker (Escobar *et al.*, 2000). In the United States, field trials of transgenic walnut have been ongoing for

more than 15 years under Animal and Plant Health Inspection Service (APHIS) permits. These involve trees expressing genes for insect resistance, crown gall resistance, and differences in tree architecture (McGranahan and Leslie, 2006).

2.1.1 General protocol

Walnut is transformed by inserting genes into multiplying somatic embryo cultures. *Agrobacterium tumefaciens* readily infects young proliferating somatic embryos (McGranahan *et al.*, 1988b). Since new embryos develop from single epidermal cells (Polito *et al.*, 1989) transformed cells produce entirely transformed embryos and chimeras are eliminated. Embryos can be germinated to produce uniformly transformed plants. This method was used to produce trees that were field tested for the first time in 1989. Walnuts were the first transformed woody fruit or nut tree to be field tested. These trees bore nuts and the introduced genes were found to be both stably incorporated and inherited in a simple Mendelian fashion. Several independent transgenic lines can be obtained from a single embryo indicating multiple infection sites on the surface of the walnut embryo (McGranahan *et al.*, 1990a). This feature makes the walnut transformation system very efficient. Detailed protocols for the transformation of walnut have been published (Dandekar *et al.*, 1989; Leslie *et al.*, 2006b).

The *A. tumefaciens* strains that have been shown to work efficiently include the disarmed derivatives (e.g., EHA101) of the tumorigenic A281 strain that contains the Ti plasmid pTiBo542 and the nonpathogenic strain C58C1 that possesses a disarmed version of the tumorigenic Ti plasmid pTiC58 (Van Larebeke *et al.*, 1974; Hood *et al.*, 1986; Dandekar *et al.*, 1988). Transformation efficiency in walnut is approximately 20–25% (McGranahan *et al.*, 1990a; Dandekar *et al.*, 1998) with low rates of embryo germination. However, multiplication by micropropagation of transformed epicotyls is successfully used to increase the amount of transformed plant material (Reil *et al.*, 1998).

The binary vector plasmids used for walnut transformation are generally derivatives of those described by McBride and Summerfelt (1990) with genes under the control of the CaMV 35S

promoter. Generally, the neomycin phosphotransferase (*NPTII*) gene is used as a selectable marker and the *uidA* gene (coding for β -glucuronidase) is used as a scorable marker. Nontransformed embryos multiply poorly and appear yellowish on kanamycin-containing medium. Embryos that multiply well and appear healthy on kanamycin can be checked for GUS activity using X-glucuronide staining (Jefferson, 1987) or GFP fluorescence (Escobar *et al.*, 2000). Transformed embryos can be germinated following desiccation (Leslie *et al.*, 1997). This method has also been used to transform Eastern Black Walnut (Bosela *et al.*, 2004) and pecan (McGranahan *et al.*, 1993).

2.1.2 Regeneration

Because walnut somatic embryos are transformed without induction of a callus phase, and because the secondary somatic embryos derive from single cells (and thus from a single transformation event), existing tissue culture techniques can be used for the production of transgenic plantlets. As described above, somatic embryos are germinated and then can be micropropagated.

2.2 Applications of Transgenic Technology

2.2.1 Codling moth: Bt cry protein

Larvae of the codling moth (*Cydia pomonella*) are the key insect pests of walnut. Since there is little genetic resistance available in the germplasm, application of chemical pesticides is the main method of controlling this insect. To find a candidate gene to combat this pest, various insecticidal crystal proteins (ICP) from *Bacillus thuringiensis* were tested by incorporating the protein into insect diet (Vail *et al.*, 1991). Because these proteins are not toxic to mammals, they could be safely expressed in nuts. The *cryIA(c)* protein was found to be the most effective but transformation of walnut using the bacterial gene encoding this protein failed due to lack of expression (Dandekar *et al.*, 1994). This was a result of codon bias in the bacterial gene sequence, which resulted in very low levels of protein translation (Dandekar *et al.*, 1994; Leslie *et al.*, 1997). A synthetic gene correcting this problem

worked very well and high levels of codling moth mortality were observed when larvae were fed transgenic embryos (Dandekar *et al.*, 1998). Transgenic trees from these lines of the commercial cultivar "Chandler" are currently being tested in the field (Leslie *et al.*, 2001).

2.2.2 Chalcone synthase

The enzyme chalcone synthase catalyzes the first and rate-limiting step in the biosynthesis of flavonoid compounds in plants (Claudot *et al.*, 1997). It was hypothesized that flavonoids and flavonols might inhibit rooting and that, therefore, a reduction of these compounds through manipulation of this key enzyme could result in improved rooting of micropropagated plants (El Euch *et al.*, 1998). To achieve this, an antisense construct of the *chs* gene under the control of the CaMV 35S promoter was introduced into *J. regia* hybrid somatic embryos using *Agrobacterium*-mediated transformation. Lines that showed significant reduction in *chs* gene expression also had a concomitant decline in flavonoid compounds. Transformed microshoots were observed to have apical necrosis and large basal callus production. The rooting ability of the transformed microshoots was generally better than nontransgenic controls, but was seen to be variable (El Euch *et al.*, 1998).

2.2.3 Crown gall

Crown gall is a serious problem for many fruit, nut, and ornamental crops, greatly diminishing productivity. Walnuts are very susceptible to this disease. Losses are incurred from both contaminated nursery stock and infected orchard trees. Current prophylactic measures and mechanical removal of galls have not adequately controlled the problem.

Pathogenic *A. tumefaciens* transforms infected plants with the genes *iaaM* (tryptophan monooxygenase), *iaaH* (indole-3-acetamide hydrolase), and *ipt* (isopentenyl transferase). The *iaaM* and *iaaH* gene products convert tryptophan into indole-3-acetic acid, an auxin, while the *ipt* gene product catalyzes the production of isopentenyl AMP, which is converted to cytokinins by endogenous

plant enzymes. The resulting overproduction of auxin and cytokinins induces proliferation of callus tissue at the wound site, resulting in the development of large galls (Britton *et al.*, 2007).

To engineer resistance to this pathogen, a binary vector plasmid containing inverted repeats of portions of the *iaaM* and *ipt* genes was constructed and transformed into walnut using disarmed *A. tumefaciens* (Escobar *et al.*, 2002). Constitutive expression of this construct induces RNA interference mediated degradation of the *iaaM* and *ipt* transcripts, demonstrating for the first time the use of RNA interference to generate resistance to a major bacterial disease (Escobar *et al.*, 2001). Because the construct and the oncogenes do not need to have perfect homology for silencing to be effective, the resulting transgenic microshoots are resistant to a very wide range of *A. tumefaciens* strains, thus indicating a broad-spectrum durable resistance (Escobar *et al.*, 2002). Plants grown from these lines are expected to begin field trials in 2007.

2.2.4 Aflatoxin

Walnut is a tree crop whose nuts can be contaminated with aflatoxins, which are carcinogenic and teratogenic chemical compounds synthesized by members of the fungal genus *Aspergillus*. Many countries that import walnuts have set total aflatoxin action threshold levels at four ppb, significantly below the US Food and Drug Administration recommendation of 20 ppb. Because fungal infections often follow damage due to feeding of insects, such as codling moth larvae, an important objective of breeding and genetic engineering is to develop lines that demonstrate insect resistance (Campbell *et al.*, 2003). As discussed above, the engineering of walnuts to produce the insecticidal cryIA(c) protein shows promise to reduce codling moth damage and subsequent fungal infection.

It has also been discovered that kernels of the “Tulare” variety of Persian walnut are able to suppress the production of aflatoxin (Mahoney *et al.*, 2003). Evidence points to the high concentration of gallic acid in the pellicle (seed coat) as the factor that inhibits aflatoxin generation. The gene encoding shikimate dehydrogenase (SDH), the enzyme responsible

for gallic acid production, has been cloned. Somatic embryos of the cultivar “Chandler” were transformed to overexpress the *SDH* gene, resulting in the production of a high concentration of gallic acid and increased inhibition of aflatoxin production (Muir, 2005). Plants of these are in the greenhouse and will be tested when nut production commences.

2.2.5 Rhizogenes

It has been hypothesized that transformation with pathogenic *Agrobacterium rhizogenes*, or some of the genes contained in the *A. rhizogenes* Ri (root-inducing) plasmid, might improve the rootability of micropropagated walnut shoots. Transformation of *J. regia* with the wild-type strain 1855 NCPPB did induce rooting under certain media conditions, particularly in the presence of exogenous IBA (indolebutyric acid) (Caboni *et al.*, 1996; Falasca *et al.*, 2000).

The Ri plasmid genes *rolA*, *rolB*, and *rolC* (*rolABC* genes) have also been cloned from the Ri plasmid of *A. rhizogenes* strain A4, and placed in a binary vector under the control of their original promoters. This vector was introduced into *A. tumefaciens*, which was then used to transform somatic embryos of the *J. hindsii* × *J. regia* (Paradox) clone PX1. The resulting transformants were grown into stock plants. It was found that the presence of the *rolABC* genes altered canopy architecture, producing bushy canopies of dense foliage, with leaves that were wrinkled and slightly curled. However, there was no increase in rootability. When a *J. regia* scion cultivar (“Chandler”) was grafted onto the transgenic rootstock, there was no difference in growth, compared to scions grafted onto nontransformed rootstocks (Vahdati *et al.*, 2002).

3. FUTURE PROSPECTS

Currently, several lines of transgenic walnut rootstocks and scions, containing the genes described above, are in field trials in California. The commercial availability of transgenic rootstocks, however, is not expected for several years, after the completion of field trials. Acceptance of transformed rootstocks is expected due to grower

desire for traits such as disease resistance. By transforming only the rootstock, no transgenic pollen or nuts are created, eliminating the opportunity for the escape of introduced genes into the wild. It is unlikely that transgenic walnut scions will be commercialized unless there is consumer acceptance in many parts of the world (McGranahan and Leslie, 2006).

However, the techniques of nontransgenic biotechnology will continue to be used. These include genetic markers for detecting sensitivity to CLRV, which is being used to breed hypersensitive *J. regia* and the fingerprinting of all walnut cultivars to allow identification through DNA analysis, so that all the selections in the breeding program will have unique published fingerprints (Dangl *et al.*, 2005).

Improvements to walnut genomics are also on the near horizon, with thousands of expressed sequence tags being generated in current and future projects, both for *J. regia* cultivars and *J. hindsii* rootstocks. It is likely that, by 2010, a physical map of the *J. regia* chromosomes will be produced in preparation for eventual genome sequencing.

1. INTRODUCTION

1.1 History, Origin, and Distribution

The area of origin of *Citrus* is believed to be Southeastern Asia, including South China, the Indo-Chinese peninsula, Northeastern India, and Burma. This is a wide area, but attempts to localize more precisely the centers of origin of the most important *Citrus* types are still now controversial. It has become clear in recent times that only citron (*Citrus medica*), mandarin (*C. reticulata*), and pummelo (*C. grandis*) are true species within genus *Citrus*, being other important *Citrus* types, as sweet orange, sour orange, lemon, lime, grapefruit, and other mandarins originated from hybridization between these ancestral species. This view was convincingly supported by the phylogenetic study of Barrett and Rhodes (1976) who evaluated 146 morphological and biochemical tree, leaf, flower, and fruit characteristics, and it was later confirmed also using molecular markers (reviewed by Nicolosi, 2007). Therefore, Southeastern Asia would not only be the site of origin of most important *Citrus* types but also its major center of diversity. Domestication could have started in this area and expanded progressively in all directions. The genus *Citrus* is by far the most important among the Rutaceae family, but there are two other genera that have played a relevant role in citriculture, which are *Fortunella*, producing

edible fruits and commonly called kumquat, and *Poncirus*, sometimes vulgarized as trifoliate orange. All authors coincide in ascribing their origin to central China, since both genera are most cold-hardy than *Citrus* and are reported as growing wild in the Yellow river area in ancient Chinese literature.

The first historical documents mentioning the use of citrus come from China and India. Confucius describes prehistoric China in its classic “Book of History”, written ca. 500 BC, and in the “Tribute to Yu” states that the Chu and Yu were sent as annual tributes to the emperor Ta Yu (2205–2197 BC) from An Yang (north of the Yellow river) by the people of central and southern provinces, Chu and Yu being referred to *Citrus* types, most likely to mandarin and mandarin/pummelo natural hybrids, respectively. The Chu is mentioned in several Chinese classic books and also in the Bretschneider’s “Notes on Chinese Botany from Native and Western Sources” as cultivated along Yellow river central regions since 12th century BC. During the 2nd century BC, the Han emperor Wu Ti conquered and annexed the barbarian provinces of the south, and soon after, new *Citrus* types appeared in Chinese references. Kan possibly referred to sweet orange early types, Yu or Yau was then a pummelo type, and Chang was first used to describe sour orange types and later as a generic term for oranges, mainly sweet oranges. The first written reference to citrus fruits

appeared in India in the “Vajasaneyi Samhita”, a collection of sacred Brahma texts written in Sanskrit prior to 800 BC, where ancient lemon and citron types are called “jambila”.

The citron was the first *Citrus* type noticed by the Europeans and the only one known for centuries. Theophrastus describes the tree in his “Historia Plantarum” (around 300 BC) and its fruit is called “Persian citron” or “Median apple”, assuming that it was indigenous from that region. Although there are conflicting opinions on how citron arrived to Europe, most authorities agree in supporting that Alexander the Great brought it to Greece when returning from India (about 300 BC). According to a very famous Greek myth, one of the labors of Heracles was the theft of the golden apples of Hesperides, in which golden apples would be translated as citrons. *Citrus* were called Hesperides by Roman writers. Linnaeus gave the name Hesperideae to an order containing the genus *Citrus*. Nowadays, in botany the term hesperidium names a berry whose fleshy parts are divided into segments surrounded by a rind or hard shell, also in allusion to the golden apples of the Hesperides garden. Hebrews were also attracted by this “Persian tree” and it was adopted for worship during the feast of the Tabernacles, playing an important role in Jewish religious rituals. Latin writers as Vergil and Pliny later cited the citron and it was probably introduced to southern regions of Italy during the 1st century AD. Greeks and Romans held the citron in high esteem because of its delicate and penetrating fragrance. It was used both as a perfumant and moth repellent. It was not extended further in the continent until many years later (15th century) likely due to its cold sensitivity.

Although old mosaics indicate that orange and lemon were known by Romans, spread of sour orange and lemon in Europe through India, western Asia, and North Africa is due to the expansion of the Arab empire. The Crusaders further extended these and other *Citrus* types as limes and pummelos into Europe. It is not clear for historians when sweet orange first appeared in this continent, but it became widely spread only after the Portuguese established the commercial route with India and China in early 16th century. Before then, orange types were bitter and used mainly as condiments. Therefore, *Citrus* might be introduced into Europe many times at various periods of history by successive invaders and

traders, each being new introduction of increasing quality in terms of edibility and fragrance. There were attempts to establish *Citrus* trees in northern areas of Europe since the 1st century AD, but frost injury caused limiting problems. Because of this, *Citrus* types were cultured in special protected houses, first known as “stanzone per i cidri” and later as orangeries (14th century), which were the predecessors of greenhouses. Mandarin types, which were widely known and cultivated in Southeast Asia from ancient times, were not introduced to Europe from China until the 19th century.

There are many written references of *Citrus* cultivation in Japan since the 1st century AD, citrus being mostly referred to mandarin types. *Poncirus* was brought from China around the 8th century, but pummelo and sweet orange were introduced in Japan by Spanish and Portuguese travelers just in the 15th century. The origin of most popular satsuma mandarin from Japan is uncertain but it was not until the end of 19th century that it became expanded nationwide and commercialized (Mizutani, 2006).

Columbus took seeds of oranges, lemons, and citron to America on his second voyage, which arrived at Hispaniola (Dominican Republic and Haiti) in 1483. It was soon brought to other islands and continental America where citrus trees were fully adapted, spread widely, and become very abundant and even feral in some places of tropical/subtropical climate. Citrus were brought to Florida by the early Spanish explorers sometime between 1513 and 1565. About the same time, *Citrus* fruits were introduced into Brazil by the Portuguese. Portuguese travellers also introduced *Citrus* in West Africa while sweet oranges were the first *Citrus* introduced in South Africa by the Dutch colony in 1654. Citrus was first planted in Australia by the colonists of the First Fleet who brought oranges, limes, and lemons from Brazil. Oranges and lemons were first planted in California around 1769, after the settlement of Franciscan missions at San Diego area.

Due to their apomictic character, most *Citrus* varieties were propagated as seedlings during many centuries. In the case of monoembryonic genotypes, propagation by seeds led to generation of a lot of genetic variation and horticultural diversity, as it is exemplified by the high number of different mandarin types that have been grown

in China and Japan during many years. Although there are ancient Chinese references reporting the graft of mandarins onto *Poncirus trifoliata*, grafting only became a common practice in citriculture from the mid-19th century, after sweet orange seedlings grown in Europe were seriously affected by *Phytophthora* epidemics. Nowadays, the citrus industry relies on trees composed of two different genotypes: a mature fruit-producing *Citrus* scion grafted onto a highly apomictic juvenile rootstock.

Most of the information compiled in this section comes from Webber (1967) and Cooper (1982) where more detailed information on the origin and history of *Citrus* can be found.

1.2 Botanical Description

1.2.1 Taxonomy

The genus *Citrus* is one of the 33 genera in the subfamily Aurantoideae of the family Rutaceae. Within this subfamily, most taxonomists recognize that “true citrus fruit trees” belong to the tribe Citreae, subtribe Citrinae, with three genera of economic importance: *Poncirus*, *Fortunella*, and *Citrus*. The taxonomy of the genus *Citrus* is controversial. The system most commonly used comes from the classification of Swingle with modifications provided by the much more complex Tanaka’s classification. While Swingle recognizes 10 and 6 species, respectively, in the two subgenera *Citrus* and *Papeda* (Swingle and Reece, 1967), Tanaka identifies up to 157 species in different groups and subgroups (Tanaka, 1954).

From the 10 *Citrus* species designated by Swingle, 8 are of commercial importance: *C. sinensis* (L.) Osb. (sweet oranges), *C. reticulata* Blanco (mandarins), *C. paradisi* Macf. (grapefruits), *C. grandis* (L.) Osb. (pummelos), *C. limon* (L.) Burm. f. (lemons), *C. aurantifolia* (Christm.) Swing. (limes), *C. aurantium* L. (sour oranges), and *C. medica* L. (citrons).

Tanaka’s system is better adapted to horticultural traits paying also special consideration to cultivated species. This concerns to *Citrus* genotypes that are widely cultivated and of high economic importance, such as clementine mandarins (*C. clementina* Hort. ex Tan.), satsuma mandarins (*C. unshiu* (Mak.) Marc.), or Rangpur

lime (*C. limonia* (L.) Osb.) among others, for which most citrus researchers use the Tanaka’s classification.

Based on biochemical and molecular marker data, there are only three true *Citrus* species: citron, mandarin, and pummelo. Since the three ancestral species reproduce only sexually and are original from the same geographical area, several generations of hybridization among these species would generate the highest levels of genetic diversity within the genus *Citrus* and sexually compatible relatives. The appearance of facultative apomixis together with the selection of specific genotypes propagated as seedlings by men gave rise to most of the *Citrus* types currently cultivated. Obviously, this has led to a narrow genetic base within *Citrus*, in spite of the wide diversity of horticultural traits that can be found in the cultivated varieties.

Isozymes, organelle genomes, microsatellites, restriction fragment length polymorphism (RFLP), random amplified polymorphic DNA (RAPD), and sequence-characterized amplified region (SCAR) analyses have provided important clues on the genetic relationships among *Citrus* types. Concerning economically important *Citrus* “species”, sweet oranges are thought to be hybrids between mandarin and pummelo, sour oranges would come from a mandarin genotype introgressed with genes from pummelo, which is the maternal donor, lemon would originate from citron and sour orange (female parent), and lime would also have citron as one of the parents and a *Papeda* (*Citrus micrantha* Webster) species is proposed to be the other parent. Grapefruit is a very recent species, first described in Barbados in 1750, and originated from a natural hybridization between pummelo and sweet orange probably followed by introgression with pummelo (reviewed in Nicolosi, 2007).

1.2.2 Citrus biology: some clues on growth and development

All *Citrus* types are evergreen and do not show winter dormancy but just a bud-resting period. However, the *Poncirus* relative is deciduous, showing winter leaf abscission and bud dormancy. *Citrus* species show a sympodial pattern of growth, based on flushes of growth in which the shoot

apical meristem senesces after the production of several leaves and axillary buds. The closest bud to the senescent shoot apical meristem drives the following growth flush. Whereas in subtropical conditions, three to five flushes occur per year, in tropical areas shoot growth occurs almost uninterruptedly. These growth pattern and number of flushes per year is maintained in plants grown under temperature-controlled greenhouses. However, it can be forced up by increasing day length artificially. Moreover, the elongation of the shoot can be manipulated by controlling light intensity.

Citrus shoots develop several axillary buds in the axil of each leaf, together with an axillary thorn. Shoot length is related with the genotype and the vigor/age of the shoot. Presence of thorns is commonly considered as a juvenile character, but there are genotypes showing thorns being fully mature, as for example some lemon varieties. There are also juvenile genotypes without thorns, such as Cleopatra mandarin. Leaves are unifoliate and in most species the petioles are winged. *Poncirus* shows trifoliate leaves, reminiscent of other *Aurantoideae* genera with composite leaves. Elongated leaf shape and larger petiole wings are considered juvenile characters.

Flower bud differentiation is induced photoperiodically in subtropical areas when the day becomes shorter during winter months. Cold temperatures are also important in floral induction. In the deciduous *Poncirus*, flower bud induction is initiated during late summer. In tropical areas without photoperiod changes, water stress is the major flower-inducing signal. In *Citrus*, blooming usually occurs in spring, following flower development. As evergreen, reproductive and vegetative developments are intimately related, and four main shoot types can be distinguished: vegetative shoots, leafy inflorescences, leafless inflorescences, and solitary flowers. *Poncirus* and *Fortunella* also flower in spring but usually sooner and later than *Citrus*, respectively.

The citrus fruit is a hesperidium, namely a berry arising from growth and development of the ovary, consisting of fleshy parts divided by segments, the whole being surrounded by a separable skin. It is composed of two major regions: the pericarp, commonly known as the peel, and the endocarp, often called the pulp.

The pericarp is composed of external colored peel known as flavedo, and the internal usually white layer known as albedo. Citrus fruits are nonclimacteric, ethylene changes being extremely low during fruit development. During maturation the dark green, photosynthetically active flavedo transforms its chloroplasts into carotenoid-rich chromoplasts. On the other hand, maturation of the pulp is characterized by a decline in acidity and an increase in sugars, the ratio of both components being used to define the “maturity index”. A good summary on citrus biology can be found in Spiegel-Roy and Goldschmidt (1996).

1.3 Economic Importance

Citrus is the most important fruit tree crop in the world, with a production of more than 105 million tons in 2005 (FAO, 2006). It is grown in more than 130 countries all over the world, mainly in tropical and subtropical areas (approximately 40° latitude in each side of the equator) where favorable soil and climatic conditions occur, extending over 7.6 million hectares. Major producing countries include Brazil, the United States, China, Spain, Mexico, India, Iran, Italy, Egypt, Argentina, Turkey, Japan, Pakistan, South Africa, Greece, Thailand, Morocco, Israel, Indonesia, Korea, and Australia, from major to minor. The first five countries account for about 55% of the world production.

Sweet orange represents more than 55% of total citrus production, being marketed as fresh fruit or as processed juice. Traditionally, oranges were consumed as fresh fruits but in the last 30 years consumption of processed oranges (mainly as concentrated fruit juice) has increased extraordinarily all over the world, and especially in Europe and the United States. It represents the primary force supporting expanded world consumption and is the basis of Brazilian and Florida citrus industries. Brazil and the United States produce almost 45% of sweet orange in the world and about 60% is processed.

Mandarins, including clementines, tangerines and satsumas, represent about 20% of total citrus fruit production. The first producer is China, followed by Spain and Japan. Most mandarins are intended for the fresh market and are generally consumed in the country of

production, with the important exception of Spain that is the first producer of clementines and exports more than half of its production. Japanese mandarins are nearly all satsumas. It is difficult to track the production of processed mandarin since most juice is blended with orange juice. There is an increasingly important industry of production of canned fruit segments (mainly from satsuma) developed in Japan and Spain, and more recently in China that has become the first producer.

Lemons and limes differ from other citrus types in that they are typically consumed processed or mixed with other foods. Whereas lemons are widely adapted to different climates, limes are highly sensitive to cold, being grown exclusively in tropical climates. Mexico is the first producer and exporter of limes with a production of almost 2 million tons in 2005, followed by Brazil. India is a major producer of both lemons and limes. Argentina is the first world producer and exporter of lemons. The United States, Spain, and Italy are also major producers of lemon. There is an important industry of processed lemon and lime fruits with the juice and essential oils used as flavorings in beverages and foods.

Production of other citrus types is much smaller compared to the four major groups, no more than few hundred tons in the case of pummelos, citrons, and kumquats, mostly are commercialized in local Asian markets. Processed *Citrus* fruits have many uses apart from those mentioned above. Sour orange fruits are used to produce marmalade and flowers are used to extract neroli oil, which is highly appreciated in perfumery. Peel essential oils, mainly monoterpenes, have a wide industrial use as food additives to provide a citrus flavor, as a fragrance in perfumes, air fresheners and personal care products, and as a natural replacement for petroleum-based solvents in paints and cleaning products. By-products of concentrated citrus fruit juice are used as molasses for animal feed. There is an increasing utilization of citrus trees as ornamental plants in the United States and Europe.

Citrus fruits have been shown to possess many constituents, which have important effects on the human health: vitamin C, carotenoids (as provitamin A), folic acid, flavonoids, monoterpenes/essential oils, limonoids, and others.

1.4 Citrus Scions and Rootstocks: Needs for Genetic Improvement

1.4.1 Origin of currently cultivated citrus scions and rootstocks

Citrus are diploid species having a haploid chromosome number of 9 and an approximate genome size of 0.9 pg (picogram) (~385 Mb). Most *Citrus* rootstocks and varieties grown commercially nowadays have been originated by budsport mutations and chance seedlings and have been selected directly by growers due to their excellent fruit quality, performance, and stress resistance.

In case of sweet oranges, there are two major types: blond oranges, mainly used for juice production, as the most representative Valencia orange, and navel oranges, mainly used for fresh consumption. Valencia orange was probably originated in Azores or Portugal as a mutant from the superior class of oranges brought by the Portuguese from China in the early 16th century. Many nucellar clones and likely budsport mutations of outstanding interest have been generated from the original Valencia, which are currently the basis of the Brazilian and Florida citriculture. The origin of navel orange is uncertain but it has been claimed that it was generated as a limb sport from the blond variety Selecta at Salvador de Bahia (Brazil). Worldwide expansion of this type started after it was brought to the United States and renamed as Washington navel at the end of 19th century. Many early and late-ripening bud mutants have been found covering all seasons with one of the most excellent fresh fruit types achievable in markets. A third group of minor importance is that of blood oranges, characterized by the accumulation of anthocyanins in the flesh and juice, red pigment synthesis being usually dependant on low night temperatures. They probably originated in the Mediterranean area as mutants from blond oranges. Nowadays, blood oranges are only important in Italy, Tarocco being their most popular selection.

Natural and man-made mandarin hybrids have been cultivated in China and Southeast Asia during many centuries. Two of the most commercially successful mandarin types in current times are satsumas in China and Japan, and clementines in Spain and Morocco. The original

satsuma was most probably generated as a chance seedling in Kyushu Island (Japan) around 15–16th century. Many early and late maturing, small and larger fruited types are commercially relevant and all of them have been generated as limb sports, bud sports, or nucellar seedlings from pre-existing scions. Clementine first appeared in the garden of an orphanate near Oran (Algeria) and it was discovered by Father Clement Rodier as a seedling from a cross between a Mediterranean mandarin and an ornamental sour orange known as Granito, according to historical records. However, molecular markers data support that it was originated from a mandarin \times sweet orange cross (reviewed by Nicolosi, 2007). It is not strange that the first describers were confused about the actual pollen donor. Clementine was introduced into Spain from Algeria in 1925, and since then many excellent bud mutants of different fruit size, shape, color and maturing season have been found and propagated, constituting the main basis of the Spanish citrus industry.

Another natural hybrid mandarin is the Ponkan, widely cultivated in Asian citrus countries and in Brazil. Some other mandarin cultivars of relative importance that were originated as chance seedlings are Dancy, from Florida, and Ellendale and Imperial, found in Australia, all in the 19th century. “Murcott” is most probably a tangor (mandarin \times sweet orange) of unknown parentage cultivated in Florida, Brazil, Argentina, and Japan. Another important tangor of natural hybrid origin is “Ortanique”, discovered in Jamaica around 1920. A more recent natural hybrid is “Afourer” or “Nadorcott”, found recently in Morocco (most probably a “Murcott” \times clementine hybrid), which is considered the most significant new mandarin variety currently available.

All important common varieties of lemon and lime are natural hybrids, chance seedlings or budsport mutations selected by men either in ancient time in Southeast Asia or since the 19th century in other major citriculture areas.

Regarding rootstocks, Rangpur lime is the predominant one in Brazil, due to its combined tolerance to several important biotic and abiotic stresses. It is an ancient Asian natural hybrid. *P. trifoliata*, a true species, is widely used in several parts of the world, mainly in Asia, especially due to its cold-hardiness and semi-dwarfing abilities.

Importantly, both are resistant or highly tolerant to the major pathogens *Phytophthora* spp. and *Citrus tristeza virus* (CTV). Other relevant citrus rootstocks, as sour orange, Cleopatra and Sunki mandarins, rough and Volkamer lemons, and alemow or *Citrus macrophylla* are ancient natural hybrids of Southeast Asian origin.

In spite that present-day citriculture is based on cultivars that grower directly selected from the wild or from the orchards, they usually have outstanding quality. This makes very difficult the obtention of new improved cultivars, especially in the case of scion varieties for the fresh fruit market. Citrus rootstocks and varieties of the world are extensively detailed by Saunt (2000).

1.4.2 Needs for genetic improvement

Many different citrus genotypes are commercially grown in a wide diversity of soil and climatic conditions, implicating that trees are subjected to important abiotic and biotic stresses that limit the production and, in some instances, the use of certain rootstocks and varieties. The main abiotic stresses are acid, alkaline, and salty soils, flooding and drought, freezing, and high temperatures.

Citrus trees are also affected by many pests, diseases caused by nematodes, fungi, oomycetes, bacteria, spiroplasmas, phytoplasmas, viruses and viroids, and diseases of unknown etiology. Some diseases are spread throughout the world, as those produced by the oomycete *Phytophthora* spp., or by the CTV, which preclude the use of certain excellent rootstocks, and severely restrict fruit production and quality of important varieties in some countries. Other diseases are restricted to specific geographic areas, as those caused by the bacteria *Xylella fastidiosa* or by citrus sudden death associated virus in Sao Paulo state (Brazil). There are also diseases spread in most citrus areas, as citrus canker, caused by the bacteria *Xanthomonas axonopodis* pv. *citri*. Whereas Brazil has been able to implement a quite successful eradication program, the bacterium is currently expanding without control in Florida. Finally, there are diseases that were locally important but in more recent times have become widely spread and are seriously threatening important citricultures, as it is the case of the Huanglongbing caused by the bacterium *Candidatus Liberobacter asiaticum*,

which affects all citrus varieties. It has impeded the development of citriculture in certain Southeast Asian countries and at present day is devastating millions of trees in Florida and Brazil. In the cases of these three bacteria there are no means for efficient control. At the same time that citrus industry is threatened by important biotic and abiotic stresses, markets demand fresh fruit and juice of increasing quality. In this situation, genetic improvement of citrus has a very high priority.

Major current goals of rootstock breeding are resistance to CTV and *Phytophthora* spp., cold-hardiness in citrus areas as Japan, Florida, or New Zealand, scion size-controlling abilities, higher tolerance to calcareous, and saline soils in areas with poor-quality water, and resistance to the citrus and the burrowing nematodes, particularly in Florida. Scion breeding is mainly focused in resistance against major pests and diseases, and in fruit quality aspects. For the fresh fruit market, major goals include adequate size for each citrus type, easy peeling, seedlessness, attractive color and aroma, compensated acid/sugar content in the fruit, extension of the maturity season for all year round supply, and good storage and shipment. When the fruit is going to be used for juice production, prime goals are juice content of the fruit, good color, and lack of bitterness.

1.5 Limitations of Conventional Breeding, Achievements, and Rationale for Transgenic Breeding

1.5.1 Biological limitations of citrus breeding

Conventional breeding by hybridization has important limitations. *Citrus* species have a complex reproductive biology. Most genotypes are facultative apomictic, which means that adventitious embryos initiate directly from maternal nucellar cells, limiting or precluding the development of less vigorous zygotic embryos. Although this is the basis for propagation of citrus rootstocks, apomixis seriously limits the recovery of sexual progeny populations in breeding programs. Some important genotypes have total or partial pollen and/or ovule sterility and cannot be used as parents in breeding programs; for example, most navel oranges are male sterile

while satsuma mandarins and most navel and Valencia oranges are female sterile. There are many cases of cross- and self-incompatibility. Clementines, grapefruits, and certain important lemons are self-incompatible, and many hybrids between self-incompatible cultivars are also cross-incompatible. They have a long juvenile period and most species need at least 5 years to start flowering in subtropical areas, and usually several years more to achieve fully mature characteristics. Citrus have high heterozygosity, there is a lack of basic knowledge about how the most important horticultural traits are inherited, and they show quantitative inheritance of important characters, many of them related to fruit quality and maturity time. All these features together with their large plant size have greatly impeded genetic improvement of citrus through conventional breeding methods. Moreover, sources of efficient resistance against important pathogens as *Candidatus* L. asiaticum and *X. fastidiosa* have not been found in the citrus germplasm.

1.5.2 Breeding goals and new tools for citrus improvement

In principle, breeding objectives in citrus are different depending on whether improved rootstocks or scions would like to be generated. Citrus trees, mainly sweet orange, were mostly produced from seedlings until mid-19th century, when *Phytophthora* spp. was recognized as a major disease of trees first in Azores (1840) and later in France and Spain. There are records indicating that sweet orange trees were grafted onto different rootstocks as citron, lemon, sour orange and other sweet orange genotypes in certain citrus areas of Spain. After spreading of *Phytophthora* spp. in Spain, only scions grafted onto sour orange remained alive (Wolffenstein, 1880). Since then, all citrus trees were budded onto this rootstock, which is not only resistant to the oomycete pathogen but also provides excellent agronomic attributes, particularly fruit yield, quality, rusticity, and tolerance to calcareous and saline soils. Thus bud grafting of scion varieties onto sour orange became a universal practice. Between 1910 and 1930, trees grafted onto sour orange started to decline with a disease later identified as caused by CTV. Since then,

different citrus genotypes and relatives have been used as rootstocks depending on the requirements of each citriculture area, but very few of them were originated in breeding programs. The first recorded artificial hybridization of citrus was carried out by Swingle and Webber in Florida in 1893 with the aim of incorporating resistance to diseases, but a severe freeze destroyed most of the seedlings. Then, they decided to use the cold-hardy *P. trifoliata* as a parent in crosses to try to incorporate higher cold tolerance to citrus scions. None of the progeny trees combined hardiness with good fruit quality. However, the excellent Carrizo and Troyer citrange hybrids (sweet orange \times *P. trifoliata*) rootstocks resulted undeliberately from these crosses. Both hybrids are highly tolerant to CTV and *Phytophthora* spp., and are widely used as rootstocks in countries as Spain and the United States. Another rootstock hybrid obtained in the same program, though released in 1974, was the Swingle citrumelo, coming from a grapefruit \times *P. trifoliata* cross performed in 1907. It is widely used in Florida and South Africa. All other important rootstocks used now-a-days are true species or ancient natural hybrids.

Very active variety hybridization programs were performed along 20th century in most citrus-growing countries, but none of the important scion varieties cultivated at present day came from such programs though some hybrid scions of relative importance were generated. In Florida, grapefruit \times mandarin hybrids gave rise to the “Orlando” and “Minneola” tangelos. Clementine \times these tangelos yielded a number of hybrids of some importance as “Nova”. In California, Frost performed interesting crosses among different mandarin types between 1914 and 1916, and obtained the “Kinnow” mandarin hybrid (King mandarin \times Mediterranean mandarin), widely cultivated in Pakistan and India. “Fortune”, a hybrid of clementine \times Dancy mandarin made by Furr in California in 1964, has been the most important late mandarin hybrid in Spain in the last two decades of the 20th century. “Kiyomi” is a tangor (satsuma \times sweet orange) obtained in Japan and released in 1979. Ponkan \times “Kiyomi” recently gave rise to “Shiranui” that is probably the best success of hybridization breeding programs in Japan.

Artificial induction of genetic changes was initiated in 1935 in the United States by treating seeds with x-rays. Then the most important results

of irradiation programs came from Henz, who obtained several thousand plants from irradiated seeds and budwood from grapefruit and Valencia orange in Texas, resulting in two of the most widely grown pigmented grapefruit varieties of present times. “Star Ruby” was produced by irradiating seeds from the Hudson variety in 1959, and “Rio Red” was selected as a bud mutation of a tree obtained after irradiation of budwood from a “Ruby Red” seedling (see also **Grapefruit**). More recently, irradiation programs have been carried out for the generation of seedless mandarin hybrids. Examples of recent highly promising seedless releases are “Orri”, generated from the Israeli hybrid “Orah” (“Temple” \times “Dancy”), and “Tango”, originated from irradiated “Afourer”.

Although diploidy is the prevalent state in citrus, tetraploids spontaneously arise due to chromosomal duplication in nucellar cells, which are able to generate embryos and plants, their frequency being highly dependent on genotype and environmental conditions. Tetraploidy has been also induced by treating nucellar callus, and caulinar apices (for monoembryonic cultivars) with colchicine. Some authors have proposed the use of tetraploid citrus as semi-dwarfing rootstocks. Nevertheless, tetraploid genotypes have been mostly used to generate triploids in crosses with diploid parents. Most triploid citrus trees are sterile, producing seedless fruit. A natural triploid variety is “Tahiti” lime (*Citrus latifolia* Tan.), increasingly important for Mexican citrus industry. Seedlessness is very difficult to obtain by conventional hybridization. Production of triploid hybrids is currently the most promising approach to obtain seedless cultivars that do not produce seeds. Recovery of citrus sexual triploid hybrids ($3n = 27$) has been reported since the early 1960s after $2n \times 4n$, $4n \times 2n$, and $2n \times 2n$ crosses (Ollitrault *et al.*, 1998). In the last case, the triploid embryos are originated by the fertilization of an unreduced diploid female gamete with a normal reduced haploid male gamete. Seeds with triploid embryos are generally underdeveloped or aborted due to uneven embryo/endosperm chromosome balance, and it is very difficult to regenerate plants regularly. In addition, analysis of ploidy level of large populations of citrus plants by cytological methods is very difficult. The development of methodologies for *in vitro* culture of embryos and small seeds and for ploidy

analysis by flow cytometry is allowing a much more efficient production of citrus triploid sexual hybrids (Navarro *et al.*, 2003). Several promising triploid mandarin hybrids have been recently released in the United States and Italy.

Another promising technology to generate tetraploid breeding parents is somatic hybridization. It allows producing somatic hybrids that incorporate genomes of the two parents without recombination, thus avoiding the problem of the high heterozygosity in citrus. Somatic hybrids are generally produced from the fusion of protoplasts isolated from embryogenic callus or suspension cultures of one parent with leaf-derived protoplasts of the second parent. Protoplast fusion is induced either by polyethylene glycol (PEG), electrically, or by a combination of both methods. After fusion, the embryogenic parent provides to the hybrid most of the capacity of regeneration through callus formation and somatic embryogenesis. In citrus this technology has been extensively used and has many important applications, including the generation of new tetraploid hybrids, utilizable as parents for triploid breeding or directly as new rootstocks, the production of triploids from haploid + diploid somatic hybridization, and the generation of cybrids, namely new diploid hybrids with the nuclear genome from one parent and either the cytoplasmic genome from the other parent or a combination of both parents (Grosser *et al.*, 2000). There is a large somatic hybridization program in Florida, with many hybrids being tested in the field as potential rootstocks and several flowering ones are being used as pollen donors in a breeding program aimed to produce triploid mandarin hybrids (Grosser and Gmitter, 2005).

Grosser *et al.* (2002) are investigating the phenomenon of somaclonal variation as an alternative method for improving sweet orange. Somaclonal variation is defined as genetic variation that is either induced or uncovered by plant tissue culture *in vitro*. This generally slight variation could modify plant horticultural performance and give rise to new improved germplasm. They are currently field evaluating several Valencia sweet orange selections obtained through somatic embryogenesis from nucellar callus or from protoplasts, which possess the superior fruit color and quality of Valencia orange, but mature earlier or later than the standard variety.

The development of genetic markers is also providing a potential tool for citrus breeding. Linkage maps have been constructed using isozymes, RFLP, RAPD, SCARs, amplified fragment length polymorphism (AFLP), microsatellites (single sequence repeat; SSR), and cleaved amplified polymorphic sequences (CAPs). These studies have served to determine the mode of inheritance of some traits and they could be useful for early selection of the progeny and genotype identification in breeding programs. More recently, other markers as resistance gene candidates (RGCs) and single nucleotide polymorphisms (SNPs) have been developed and are currently being used in citrus breeding.

1.5.3 Rationale for transgenic breeding

In spite of the many efforts put in classical breeding programs in the last 100 years, current citrus industry relies on various groups of varieties of outstanding quality that are grafted onto a narrow diversity of rootstocks adapted to different abiotic and biotic stresses. Most of these excellent genotypes have been generated by chance, mostly as budsports but also as natural hybrids or seedlings selected by men in the wild or in orchards. In addition citrus breeding is complicated due to its complex reproductive biology. In this context, genetic transformation offers an excellent alternative for genetic improvement of citrus because it is based on the introduction of specific traits into known genotypes without altering their elite genetic background. Theoretically, it would be possible to incorporate the CTV-resistance trait into the otherwise primary sour orange rootstock, or seedlessness independent of cross-pollination into clementine mandarins. The transgene of interest could come from another *Citrus* species or relative, from another plant species, or from another organism such as a bacterium, an insect or a virus, widening the possibilities for genetic improvement. Moreover, it allows overcoming the heterozygosity, inbreeding depression, and genetic incompatibility barriers associated with hybridization. Facultative apomixis is in principle an advantage because it could be possible to use vigorous juvenile material genetically identical to the elite mature germplasm as a source of plant tissue for transformation. However, this

Figure 1 Regeneration of whole citrus plants through somatic embryogenesis and organogenesis. (a) Somatic embryo at the cotyledonary stage developing from nucellar-derived callus tissue. (b) Direct organogenesis from the cut end of an internodal stem segment

cannot be applied to important monoembryonic citrus types as Clementine mandarins. In addition, female sterility is extended in citrus cultivars making it difficult to obtain seeds (e.g., in navel sweet oranges). More important, the juvenile period of citrus is extremely long compared to other fruit trees, taking about 5 years for first flowering and fruit setting, and at least 3 years more to loose completely juvenile growth and developmental characteristics. For the purpose of genetic improvement, transformation of mature tissue then becomes necessary. Sweet orange was the first fruit tree from which adult material was transformed (Cervera *et al.*, 1998a) providing the only biotechnology-based system able to overcome the juvenility constraint of citrus breeding.

2. DEVELOPMENT OF TRANSGENIC CITRUS

2.1 Plant Regeneration: Organogenesis and Somatic Embryogenesis

2.1.1 Source plant material

Compared to other fruit trees, *Citrus*, *Poncirus*, and their hybrids are more amenable to tissue culture. The ability to regenerate whole plants from protoplasts, cell suspensions, callus, tissues

and organs has been fully established (Figure 1), and regeneration studies have been successful for different applications including recovery of pathogen-free plants (Navarro *et al.*, 1975; Navarro, 1992), ploidy manipulation (Ollitrault *et al.*, 1998), generation of new hybrids and cybrids (Grosser and Gmitter, 2005), and genetic transformation (Table 1).

Sweet orange was the first tree crop in which plant regeneration from protoplasts was achieved (Vardi *et al.*, 1982; Kobayashi *et al.*, 1983). Since then, protoplast totipotency has been demonstrated and exploited for most citrus types of interest (reviewed in Grosser and Gmitter, 2005). Embryogenic suspension cultures initiated from ovule-derived nucellar callus have been the most appropriate source of protoplasts able to regenerate plants through somatic embryogenesis.

Protoplasts were the first source of plant material used to attempt genetic transformation in citrus. Kobayashi and Uchimiya (1989) obtained transgenic callus from Trovita sweet orange by PEG treatment of protoplasts with a plasmid containing the neomycin phosphotransferase II (*nptII*) marker gene, but regeneration of transgenic plants from that callus was unsuccessful. Cell suspension cultures were originated from nucellar callus and maintained in MT (Murashige and Tucker, 1969) liquid medium with 10 mg l^{-1} 6-benzylaminopurine (BAP). Two-week-old cells

were transferred to hormone-free MT medium, and 2 weeks later were collected and subjected to protoplast isolation by incubation with an enzyme solution containing macerozyme, cellulase Onozuka, and driselase in $\frac{1}{2}$ MT salts plus mannitol as osmoprotectant. Incubation was carried out at 25 °C in a rotary shaker (25 rpm) for 16 h in dark. Protoplasts were filtered through a nylon mesh and washed with mannitol and MT plus mannitol through low centrifugation cycles to remove the enzymatic solution. Protoplasts were purified from a sucrose-mannitol gradient (Kobayashi *et al.*, 1985), suspended in a mannitol

solution and mixed with a plasmid vector solution. After 5 min, a PEG solution was added to the mixture. Dilutions were made with a glucose-containing solution to adjust the osmotic level of the mixture. Protoplasts were then cultured in MT plus mannitol medium in small Petri dishes. The plates were sealed and maintained under 16-h/day illumination (500 lux) at 26 °C. After 2 weeks, the medium was diluted with an equal volume of MT plus mannitol. Two weeks later, the medium was solidified by an equal MT plus mannitol medium supplemented with 50 mg l⁻¹ kanamycin and 1.2% agarose. After 2

months, cell colonies were transferred to MT plus 0.8% agar and 25 mg l^{-1} kanamycin for a second round of selection. Only eight colonies larger than 1 mm were able to survive the two rounds of selection. They were transferred to kanamycin-free MT medium supplemented with 5 mg l^{-1} BAP, 0.8% agar, but apparently they did not progress further. Integration of the *nptII* transgene was demonstrated in 4–5 of the callus lines by Southern blot analysis.

Vardi *et al.* (1990) produced transgenic callus from rough lemon (*Citrus jambhiri* Lush.) by PEG treatment of protoplasts with a plasmid containing the marker genes chloramphenicol acetyltransferase (*cat*) and *nptII*, and obtained several stably transgenic embryogenic lines, and at least two of them regenerated whole plants. Nucellar callus subcultured at least twice on MT was macerated in an enzyme solution containing macerozyme, cellulase Onozuka, and driselase in $1/2$ MT salts plus mannitol and sucrose. Protoplasts were isolated by sequential filtering through nylon screens, and washed several times by centrifugation at $100 \times g$ in MT plus sucrose/mannitol solutions. Washed protoplasts were resuspended and centrifuged in a Ficoll/mannitol gradient. Intact protoplasts formed a prominent band at the upper interface while the debris remained at the bottom. Then, protoplasts were collected and rewashed. For transformation, protoplasts were cocultivated with the linearized plasmid vector in a buffer medium containing PEG. Protoplasts were layered on top of a feeder layer consisting of γ -irradiated *Citrus* \times *P. trifoliata* protoplasts plated in small Petri dishes. According to Vardi and Galun (1989), the feeder layer would promote protoplast division. However, the PEG treatment delayed the initiation of cell division from protoplast-derived cell colonies, and only about 8 weeks after transformation protoplast-derived microcallus attained about 0.5 mm. Then, it was exposed to paromomycin selection ($20\text{--}40 \text{ mg l}^{-1}$) in MT plus 4% sucrose, since the more common aminoglycoside antibiotic kanamycin did not provide a reproducible inhibition curve. Green embryoids were formed from 21 callus colonies, which were picked up and plated on a medium devoid of paromomycin to promote further growth and development. Individual embryos were isolated and regenerated

to plants. Integration of the *nptII* gene in several plants and embryos was demonstrated by Southern blot analysis, as well as *cat* and *nptII* expression in putative transgenic embryos.

Hidaka *et al.* (1990) produced transformed callus of Washington navel and Trovita sweet oranges by co-cultivation of embryogenic cell suspension lines with *Agrobacterium tumefaciens*, but only one transgenic plantlet of Washington navel was regenerated. Six- to eight-year-old nucellar callus from Washington navel orange, Ohta ponkan, and Kara mandarin, and pollen-derived somatic callus from Trovita sweet orange, all of them maintaining their embryogenic potential, were transferred to liquid MS (Murashige and Skoog, 1962) medium supplemented with 0.2 M sucrose and $50 \mu\text{M}$ kinetin. Cultures were incubated at 25°C , 16-h light period, in an orbital shaker at 130 rpm, and refreshed at least three times at 2-week intervals. Seven days after subculture, cell colonies were suspended in MS-sucrose liquid medium and inoculated with *A. tumefaciens* at a ratio of 100–200 bacteria per cell colony. Two bacterial strains were used, each carrying the *nptII* or the hygromycin phosphotransferase (*hpt*) marker genes within the transfer-DNA (T-DNA) of their disarmed Ti plasmids. After 3, 5, or 7 days of co-cultivation, cell colonies were washed several times with MS plus 0.2 M sucrose supplemented with 100 mg l^{-1} kanamycin or 20 mg l^{-1} hygromycin, and then they were spread on the same medium but gelified with 0.8% agar. A second round of selection was performed with double antibiotic concentration. Aliquots from both the first and the second round of selection were spread on MS plus 0.2 M sucrose for callus proliferation, or on MS plus 0.1 M galactose and 0.1 M sorbitol for embryoid differentiation. Co-cultivation of 3 days provided the best results. Antibiotic pressure, even at low concentration, inhibited callus proliferation. However, green embryoids were formed from Washington navel and Trovita orange callus after 6–10 weeks of culture in the first selection medium. Transfer of embryoids and callus to the second selection medium precluded further progress in most cases but 15 embryoids in total were able to survive. At least one Washington navel orange embryoid was able to regenerate a whole transgenic plant, which was confirmed as *hpt*-positive by Southern blot.

Hidaka and Omura (1993) obtained transformed ponkan mandarin callus by electroporation of protoplasts, but no plants were regenerated. Ohta ponkan nucellar callus was transferred from liquid MS and subcultured at least three times at 2-week intervals. Then cell suspensions were transferred to liquid MS plus 0.1 M sorbitol and 0.1 M galactose for other three subcultures. One week after the last subculture, protoplasts were isolated according to Vardi *et al.* (1990). The maceration medium consisted of $\frac{1}{2}$ MS with 0.3% macerozyme Onozuka, 0.3% cellulase Onozuka, 0.35 M mannitol, and 0.35 M sorbitol. Protoplasts were resuspended in electroporation buffer containing 0.6 M mannitol, and plasmid DNA was added at a concentration of 20 mg l^{-1} . The plasmid used carried the β -glucuronidase (*uidA*) gene as reporter marker. Samples were subjected to electroporation with an exponential decay pulse provided by a pulse generator. After electroporation, the suspension was transferred to a buffer containing 0.25% gelrite, 0.15 M sucrose, and 0.45 M glucose. Callus colonies formed after 2 months of culture were stained with 5-bromo-4-chloro-3-indolyl- β -D-glucuronic acid (X-Gluc) for testing histochemical GUS (β -glucuronidase; *uidA*) expression. Apparently, regeneration of transgenic plants was not attempted in this study.

Yao *et al.* (1996) reported transformation of Page tangelo embryogenic cells using particle bombardment, and produced 15 transgenic embryo lines, but they did not progress further. Highly embryogenic nucellar callus was used also here as source of tissue for transformation. Cell suspensions were prepared in liquid MS without growth regulators basically as described before. They were collected on filter paper containing sorbitol + mannitol, and were bombarded with tungsten particles coated with plasmid DNA using a Biolistic PDS-1000/HE Particle Delivery System. The plasmid vector used carried the *uidA* reporter and the *nptII* selectable marker transgenes. Stably transformed cells were detected by GUS staining at 8 weeks post bombardment. Transgenic cells and callus passed through rounds of 100 and 200 mg l^{-1} kanamycin selection. Between 10 and 100 embryos were produced and transferred to germination medium, but conversion of embryos to plantlets was generally unsuccessful. Integration of the *nptII* transgene in the callus lines was demonstrated by Southern blot analysis.

J. Grosser's laboratory has used extensively protoplasts for citrus genetic transformation (Fleming *et al.*, 2000; Olivares-Fuster *et al.*, 2003; Guo *et al.*, 2005). The protoplast transformation protocol was adapted from the PEG protoplast fusion method developed by Grosser and Gmitter (1990) for citrus somatic hybridization. Cell suspensions are prepared from ovule-derived nucellar callus with high embryogenic potential in a basal medium free of growth regulators. Protoplast isolation medium must be fine-tuned for every genotype but basically consists of the three enzymes mixture, mannitol, and buffer solutions. The suspension culture is digested overnight in the isolation medium, protoplasts are purified by centrifugation in a sucrose-mannitol gradient, and resuspended in 0.6 M modified MT medium (BH3; Grosser and Gmitter, 1990). Protoplast suspension is aliquoted and plasmid DNA is added followed by a 40% PEG solution. After several cycles of incubation, centrifugation, and washings with different culture media, protoplasts are plated in small petridishes on BH3 medium, and incubated at 25°C under low light for 4 weeks. Although transgenic callus and embryoid production is generally very efficient, whole transgenic plant regeneration is difficult, and transgenic plants usually show atypical morphology. This has been attributed to the use of long-term cultures as starting materials.

Niedz *et al.* (2003) used a 2-year-old embryogenic callus line from Hamlin sweet orange for protoplast transformation by an improved electroporation method. In this case, many normal transgenic plants were regenerated as it was demonstrated by Southern blot analysis of 18 lines. In a previous report, Niedz *et al.* (1995) electroporated embryogenic protoplasts of sweet orange with a plasmid vector, but no transgenic plants were regenerated, probably due at least in part to the toxicity of the reporter marker gene used.

Li *et al.* (2002, 2003) exploited the embryogenic potential of different citrus (Ponkan, Valencia sweet orange) callus lines to attempt the *Agrobacterium*-mediated transformation system. The use of proper vector, co-cultivation, and selection conditions allowed producing whole transgenic plants at high frequencies. All relevant reports on genetic transformation of citrus through somatic embryogenesis are summarized in Table 1(A).

2.1.2 Source plant material: citrus seedling explants

Plant regeneration through organogenesis has been reported for many *Citrus* types and relatives, and from different tissues and explants, including leaf pieces, epicotyl segments, stem internodes, root segments, thin layers, and other tissues, being epicotyl and stem segments the most preferred ones. First works on citrus organogenesis reported the regeneration of whole plants from callus tissue formed from the primary explants (Grinblat, 1972; Chatuverdi and Mitra, 1974; Barlass and Skene, 1982; Edriss and Burger, 1984), likely reflecting how responsive they are to the addition of growth regulators *in vitro*. The cytokinin BAP has been essential for secondary organogenesis from disorganized callus, with auxins having only a marginal effect (García-Luis *et al.*, 1999). A promotive effect in shoot regeneration is shown at low BAP concentration range, but raising the concentration over 5 mg l^{-1} usually inhibits bud formation and shoot regeneration while enhances callusing (Moreira-Dias *et al.*, 2000). In the absence of BAP, direct shoot regeneration occurs from epicotyl and stem segments (García-Luis *et al.*, 1999; Bordón *et al.*, 2000).

In early transformation works, Moore *et al.* (1992) compared the organogenic ability of 0.7 cm leaf disks and stem segments of different lengths from *in vitro*-grown 2–4-month-old seedlings of several citrus genotypes. Stem segments of about 1 cm in length were the most effective in shoot production. Consequently, they decided to use this material as source explant for *A. tumefaciens*-mediated genetic transformation. A disarmed *A. tumefaciens* strain that contained two different transformation vectors carrying *nptII* and *uidA* marker transgenes was used in the experiments. Internodal stem segments were inserted vertically with either the basal or the apical end protruding from a medium consisting of MT with 5% sucrose, 5 mg l^{-1} BAP, and 0.8% agar, pH 5.7. The protruding ends were inoculated with an overnight culture of *A. tumefaciens* by placing a small drop of the culture on the end of the segment with a syringe. After 2–3 days of co-cultivation, explants were transferred to the same medium supplemented with the antibiotic kanamycin (100 mg l^{-1}), as selective agent, and mefoxin (200 mg l^{-1}), to control bacterial growth.

At 4 weeks, shoots started to arise from the protruding cut ends of the explants with little or no callus production. They were excised and rooted in cups containing sterile potting soil moistened with $\frac{1}{2}$ MT medium. More than 95% of the regenerated shoots were GUS-negative, suggesting that kanamycin was not a reliable indicator of transformation in this system. In addition, rooting of GUS-positive shoots was highly inefficient, so only two whole transgenic Carrizo citrange plants could be produced.

Kaneyoshi *et al.* (1994) established the first efficient protocol for transformation of seedling plant material and applied it to the generation of transgenic *P. trifoliata* plants. Importantly, they used 1 cm long etiolated epicotyl segments from 20-day-old *in vitro*-grown seedlings as starting material for transformation, because they had previously shown that epicotyl segments were highly responsive to shoot regeneration. Seeds were sterilized with 1% sodium hypochlorite solution containing 0.1% Tween-20 for 20 min, and rinsed three times with sterile distilled water. Seeds, with their seed coats peeled off, were placed on MS plus 5% sucrose and 0.8% agar, and then incubated at 27°C in darkness. A disarmed *A. tumefaciens* strain was used as transformation vector, and *nptII* and *uidA* were used as marker transgenes. Explants were immersed in a bacterial suspension at 5×10^8 cells/ml for 15 min, blotted on sterile filter paper, and transferred to co-cultivation medium consisting of hormone-free MS plus acetosyringone at $100 \mu\text{M}$ for 3 days. Then, explants were subcultured to MS plus 5 mg l^{-1} BAP, 0.1 mg l^{-1} α -naphthalene acetic acid (NAA), supplemented with kanamycin at 100 mg l^{-1} for transgenic selection, and cefotaxime at 500 mg l^{-1} to prevent bacterial growth. Explants regenerating shoots were transferred to a new medium with much reduced BAP concentration (0.5 mg l^{-1}) and increased kanamycin level (200 mg l^{-1}) to favor transgenic shoot development. GUS assays revealed that more than 50% of the regenerants were transgenic, suggesting that kanamycin was a reliable selectable marker in this system. Attempts to avoid escape regeneration by growing the explants in 200 mg l^{-1} kanamycin were unsuccessful. Elongated shoots were rooted in MS plus 0.5 mg l^{-1} NAA without problems. Efficient stable integration was demonstrated by Southern blot analysis of *uidA* gene in several transformants.

Authors claimed that this procedure permitted them to generate more than 100 transgenic plants within 2–3 months with an average transformation efficiency (transgenic shoots \times 100 per total number of explants) higher than 60%. Moreover, it has been successfully used by this and other groups to incorporate transgenes of potential interest into *P. trifoliata* (Kobayashi *et al.*, 1996; Kaneyoshi and Kobayashi, 1999; Wong *et al.*, 2001; Iwanami *et al.*, 2004; Endo *et al.*, 2005).

Peña *et al.* (1995b) used a similar protocol to transform Carrizo citrange, but it had to be modified because this genotype responded much worse than *Poncirus* to *Agrobacterium*-mediated transformation and shoot rooting. Stored seeds coming from the same tree stock were peeled, removing both seed coats, disinfected for 10 min in a 0.5% (v/v) sodium hypochlorite solution containing 0.1% (v/v) Tween-20, and rinsed three times with sterile distilled water. Five-week-old germinating seedlings were used as the starting material for genetic transformation. These seedlings were grown in MS salt solution plus 10 g l⁻¹ agar, pH 5.7, at 26 °C in darkness for the first 2 weeks, and under a 16-h photoperiod and illumination of 45 $\mu\text{E m}^{-2} \text{s}^{-1}$ for three additional weeks. An *A. tumefaciens* strain carrying a transformation plasmid with *nptII* and *uidA* marker transgenes was used as vector system for transformation. Bacteria were cultured overnight in an orbital shaker at 28 °C and 200 rpm in Luria Broth (LB) medium containing the proper antibiotics to grow the binary system. Bacterial cells were pelleted at 3500 rpm for 10 min, resuspended and diluted to 4×10^7 or 4×10^8 cells/ml in liquid inoculation medium, which consisted of MS salt solution, 0.2 mg l⁻¹ thiamine hydrochloride, 1 mg l⁻¹ pyridoxine hydrochloride, 1 mg l⁻¹ nicotinic acid, and 3% (w/v) sucrose, pH 5.7.

Either epicotyl or internodal stem segments (about 1 cm long) were cut transversely and incubated for 15 min in 10-cm-diameter plates containing 15 ml of the bacterial suspension in inoculation medium by gentle shaking. The infected explants were blotted dry on sterile filter paper and placed horizontally on plates with the same medium but gelified with 0.8% agar for a 2-day co-cultivation period. In parallel, co-cultivation was tested as in Moore *et al.* (1992), by placing a drop of the bacterial culture on the

cut end of the segments inserted vertically in the co-cultivation medium.

After co-cultivation, the explants were blotted dry with sterile filter paper and transferred to shoot regeneration medium (SRM), which consisted of MS salts, 0.2 mg l⁻¹ thiamine hydrochloride, 1 mg l⁻¹ pyridoxine hydrochloride, 1 mg l⁻¹ nicotinic acid, 3% (w/v) sucrose, 1% (w/v) agar, pH 5.7, plus 100 mg l⁻¹ kanamycin for the selection of transgenic shoots, and 250 mg l⁻¹ vancomycin and 500 mg l⁻¹ cefotaxime to control bacterial growth. This medium was supplemented with 3 mg l⁻¹ BAP. Cultures were maintained in the dark for 4 weeks at 26 °C and then were transferred to 16-h photoperiod, 45 $\mu\text{E m}^{-2} \text{s}^{-1}$ illumination, and 26 °C. A high frequency of GUS-positive shoots (55.1%) was obtained when explants were disposed horizontally in co-cultivation and regeneration medium, and when the bacterial culture was used at 4×10^7 . However, escapes (21%) and GUS-chimeric shoots (23.9%) were also produced. Attempts to root the transgenic regenerants were unsuccessful. Alternatively, shoots were excised from the explants and cut in two pieces. The basal portion was GUS-assayed and, if the reaction was positive, the apical part was grafted *in vitro* onto a nontransgenic decapitated *in vitro*-grown seedling (Navarro, 1992). This resulted in 100% recovery of transgenic shoots. About 3–4 weeks after shoot-tip grafting, plantlets were again grafted on a vigorous seedling rootstock in a greenhouse at 18–27 °C. The system resulted in transformation efficiency higher than 20% and allowed to generate Carrizo citrange transgenic plants routinely.

Gloria Moore's group also compared co-cultivation and regeneration/selection of the explants in vertical and horizontal orientations and concluded that horizontal disposition permitted to perform a better kanamycin selection. However, the use of older (3–4-month-old) seedlings, inefficient selection, and poor rooting frequency allowed them to only produce two sour orange, nine lime, and nine Carrizo citrange transgenic plants (Gutiérrez *et al.*, 1997). The same group later found that the transformation system previously established for *P. trifoliata* by Kaneyoshi *et al.* (1994) also worked for transformation of Duncan grapefruit, though at much lower efficiency (Luth and Moore, 1999; Costa *et al.*, 2002; Febres *et al.*, 2003).

Leandro Peña's group improved the transformation system of Carrizo citrange epicotyl segments by studying critically several factors affecting transformation and regeneration (Cervera *et al.*, 1998c). It was determined that co-cultivation of 3 days with *A. tumefaciens* in a medium rich in auxins and postcultivation in regeneration/selection medium for 4 weeks in darkness increased transformation efficiency to 41.3%, making possible to produce so many transgenic plants as needed in 3–6 months. The same basic procedure with more or less similar modifications has been used by other laboratories to transform Carrizo citrange (LaMalfa *et al.*, 2000; Wong *et al.*, 2001; Yu *et al.*, 2002; Kayim *et al.*, 2004), Washington navel orange (Bond and Roose, 1998), Tarocco sweet orange (Gentile *et al.*, 1998), Rio Red grapefruit (Yang *et al.*, 2000; Rai, 2006), Mexican lime (Koltunow *et al.*, 2000), Xuegan sweet orange (Yu *et al.*, 2002), Rangpur lime, Valencia, Natal, Pera, and Hamlin sweet oranges (Mendes *et al.*, 2002; Almeida *et al.*, 2003a; Boscariol *et al.*, 2003, 2006), Duncan grapefruit (Trainin *et al.*, 2005; Rai, 2006), and Ruby Red grapefruit (Rai, 2006) (Figure 2).

Pérez-Molphe and Ochoa-Alejo (1998) used *Agrobacterium rhizogenes* as transformation vector and *in vitro*-grown internodal stem segments of Mexican lime as explants. In this case, the bacteria carried the root inducing plasmid (pRi) plasmid, which is necessary for transformation and confers the characteristic hairy root phenotype, and the disarmed Ti plasmid with *nptII* and *uidA* transgenes within the T-DNA. Explants were inoculated by immersion in the bacterial culture diluted at 1×10^8 cells/ml in MS liquid medium plus B5 vitamins and 3% sucrose during 45 min, and then were placed horizontally on the same medium but with 5% sucrose and gelified with 0.8% agar for a 3-day co-cultivation period at 28 °C in darkness. Infected explants were washed for 45 min with liquid MS medium containing 750 mg l⁻¹ cefotaxime to eliminate *A. rhizogenes*. Finally, the explants were transferred to the medium used for co-cultivation but supplemented with 80 mg l⁻¹ kanamycin and 300 mg l⁻¹ cefotaxime, and with two different growth regulators treatments: without regulators or with 7.5 mg l⁻¹ BAP and 1 mg l⁻¹ NAA. In the first case, transformed roots appeared directly from the cut ends of the explants 30 days after

infection. Some explants produced shoots and roots simultaneously, but in general the frequency of regenerated shoots was low. When growth regulators were added to the regeneration medium, a pale green callus was formed at the cut ends and about 60 days later shoots were formed without hairy root phase. Transformed roots transferred to a medium with growth regulators also produced shoots at high frequency. Shoots were excised from explant and root segments and easily rooted in a medium without growth regulators. This profuse organogenic response was due to the integration and expression of the root loci (*rol*) genes from the Ri plasmid of *A. rhizogenes* in the transformed cells. The survival rate upon transfer to soil was 79%. Stable transformation was confirmed by Southern blot analysis of the *nptII* transgene. This is a rather efficient transformation system for citrus but it is not being widely used due to the integration of the T-DNA genes from the Ri plasmid in the transgenic cells. Their expression caused not only active regeneration but also important phenotypical alterations, including short internodes, reduced apical dominance, and wrinkled leaves in the transgenic plants, seriously limiting the biotechnological possibilities of the procedure.

Several groups have modified the original epicotyl transformation system with the aim of increasing the wounded area of the explants and the number of explants generated per seedling. Yu *et al.* (2002) proposed cutting longitudinally the epicotyl segments in two halves to enhance both regeneration and transformation frequency. This was used for Carrizo citrange transformation (Yu *et al.*, 2002; Kayim *et al.*, 2004), but attempts to adapt it to other citrus genotypes have been generally unsuccessful mainly due to problems associated to *Agrobacterium* overgrowth (Cervera and Peña, unpublished results; W. Guo, personal communication). Another alternative has been using thin layers of about 1–2 mm cut transversally from etiolated epicotyls. This explant type was highly organogenic, as demonstrated by Le *et al.* (1999) in *P. trifoliata*, and reduced the occurrence of escapes in Swingle citrumelo and Carrizo citrange transformation (Molinari *et al.*, 2004a, b). However, transformation efficiency is much lower than using 1 cm long explants, probably due to the toxicity of *A. tumefaciens* inoculation and co-cultivation of so small explants (Molinari *et al.*, 2004b; Cervera and Peña, unpublished results).

Although using either embryogenic nucellar callus or epicotyl segments from *in vitro*-grown seedlings as source material for transformation has led to workable transformation efficiencies for some citrus genotypes and relatives, transgenic plants were juvenile. In addition, regeneration from these materials could result in some cases in production of plants that are not true-to-type (Cervera *et al.*, 2000b; Grosser *et al.*, 2002; Cervera and Peña, unpublished results). Given the long juvenile period of most citrus genotypes, several years of cultivation would be needed before horticultural and commercial traits of the transgenic plants could be evaluated, if juvenile tissues were used for transformation. Therefore, development of transformation systems from mature plants was very important in citrus to be able to overcome juvenility.

The first approach in such direction was the use of source material coming from the greenhouse. Peña *et al.* (1995a) used 6–12-month-old greenhouse-grown (18–27°C) seedlings of Pineapple sweet orange as the source of tissue for transformation. Internodal stem segments (0.5–1 cm in length) from stem pieces (20 cm in length) were inserted vertically in SRM (Peña *et al.*, 1995b) without antibiotics and inoculated with *A. tumefaciens* carrying *nptII* and *uidA* marker transgenes by placing a drop of the bacterial culture on the cut end of the segment protruding from the medium. The explants were co-cultivated for 2 days with the bacteria, blotted dry with sterile filter paper and transferred to SRM supplemented with kanamycin, as selectable agent, and cefotaxime and vancomycin to prevent further bacterial growth. The pots were maintained in

dark at 27°C during 8 weeks and then at 25°C, 16-h photoperiod, illumination of $10 \mu\text{E m}^{-2} \text{s}^{-1}$ and 60% relative humidity during 4 weeks. Regenerated shoots of 0.2–0.3 cm height were harvested from the stem segments. Portions of 0.1–0.2 cm were excised from the shoot basal ends and assayed for GUS activity, and the remaining portions were shoot-tip grafted on Troyer citrange seedlings, as in Peña *et al.* (1995b). As transformation efficiency was low using this system (7.9%), test inoculation was done by immersion in the bacterial culture diluted at 10^7 cell/ml in SRM with BAP at 1 mg l^{-1} , and co-cultivation by disposing the explants horizontally under two different conditions: 2 days in SRM with BAP 1 mg l^{-1} , agar 0.8%, or 3 days on tomato feeder layers. Feeder plates were prepared by pipetting 2 ml of 6–7-day-old tomato cell suspensions on the surface of 25 ml of tomato cell suspension (TCS) solid medium with sterile Whatman 5 filter paper on the top in $10 \times 1.5 \text{ cm}$ (diameter \times height) plates. TCS medium consisted of MS salts, 1 mg l^{-1} thiamine hydrochloride, 1 mg l^{-1} pyridoxine hydrochloride, 1 mg l^{-1} nicotinic acid, 3% sucrose, 2 mg l^{-1} indole-3-acetic acid (IAA), 1 mg l^{-1} 2-isopentenyl-adenine (2-iP), 2 mg l^{-1} 2,4-dichlorophenoxyacetic acid (2,4-D), 0.8% agar, pH 5.7. TCSs were maintained in TCS liquid medium in a shaker at 100 rpm and 25°C and were subcultured in fresh medium every 15 days. After co-cultivation, the explants were blotted dry with sterile filter paper and transferred to SRM (BAP 1 mg l^{-1}) plates containing 100 mg l^{-1} kanamycin, for selection and 500 mg l^{-1} cefotaxime, 250 mg l^{-1} vancomycin to control further bacterial growth. The cultures were maintained in the dark for

Figure 2 Procedure for the genetic transformation of citrus plants. Aseptically germinated 4–5-week-old seedlings are used as the starting material for genetic transformation of *P. trifoliata* and Carrizo citrange. Older tissues, such as shoots from 4- to 12-month-old glasshouse-grown vigorous seedlings, are also used as the source of tissue for transformation of sweet orange, sour orange, lime, alemow, lemon, and mandarins. For transformation of mature tissues, new shoots elongated from buds, collected from trees maintained in a screenhouse (pathogen-free Germplasm Bank Collection of the IVIA), grafted onto seedlings of a vigorous rootstock grown under glasshouse conditions, are used as starting material. *Agrobacterium tumefaciens* strain EHA 105 carrying a binary plasmid is used for transformation. Bacteria are cultured overnight in an orbital shaker at 28°C and 200 rpm in LB medium containing the appropriate antibiotics. After bacterial cells are pelleted at 3500 rpm for 10 min, they are resuspended and diluted to 4×10^7 cells/ml in liquid inoculation medium. Epicotyl or internodal stem segments (1 cm long) are cut transversely and incubated for 15 min in 15 ml of bacterial suspension by gentle shaking. The infected explants are blotted dry on sterile filter paper and co-cultivated for 3 days on co-cultivation medium. After co-cultivation, explants are blotted dry with sterile filter paper and transferred to selection/regeneration medium. Cultures are grown in the dark for 2–4 weeks at 26°C and then maintained under a 16-h photoperiod with $45 \mu\text{E m}^{-2} \text{s}^{-1}$ of light intensity. Shoots usually develop from the cut ends 3–8 weeks after co-cultivation. Their transgenic nature is evaluated by histochemical assays for GUS activity or by visualizing GFP expression. The apical portions of transgenic shoots are then grafted *in vitro* onto decapitated seedlings of a citrange rootstock. Rooting is generally not easy in many citrus genotypes. New grafting of the *in vitro*-grown plants on vigorous rootstocks in the greenhouse allows the rapid acclimatization and development of putative transgenic plants. Genetic transformation is then confirmed by Southern blot analysis

15 days at 26 °C and then transferred to 16-h photoperiod, 45 $\mu\text{E m}^{-2} \text{s}^{-1}$ illumination, 26 °C, and 60% relative humidity. For Mexican lime, co-cultivation in feeder plates allowed to increase transformation efficiency twice (Peña *et al.*, 1997).

2.1.3 Source plant material: citrus mature material

Once Leandro Peña's were able to achieve 15–20% transformation efficiency working with greenhouse-grown juvenile material, they attempted transformation of mature tissues (Cervera *et al.*, 1998a). However, in the first preliminary experiments, internodal stem segments from aged mature citrus trees showed very limited regenerative potential. Then, buds from adult trees were grafted on vigorous seedlings. Buds were collected from Pineapple sweet orange trees maintained in a screenhouse (pathogen-free Germplasm Bank Collection of the IVIA) and were grafted onto seedlings of a vigorous rootstock under greenhouse conditions (18–27 °C), and newly elongated shoots were used as starting material. Stem pieces (20 cm in length) were stripped of their leaves and thorns disinfected for 10 min in a 2% (v/v) sodium hypochlorite solution and rinsed three times with sterile distilled water. Regeneration from stem segments from the first, second, and third flushes of newly grafted invigorated mature sweet orange plants was evaluated in comparison to regeneration from stem segments from juvenile plants. Results indicated that explants from the first and second flushes produced similar regeneration frequencies, significantly higher than that of the explants from the third flush. As expected, stem segments from juvenile plants produced the highest regeneration frequency. The first flush of the adult plants was selected as the source of tissue for genetic transformation experiments. Different *A. tumefaciens* concentrations and co-cultivation time and media for transformation were tested. A bacterial concentration of 10^7 cells/ml and 3-day co-cultivation in tomato feeder plates provided the best results and were used in further experiments. Regeneration/selection medium and conditions were identical to those used for transformation of juvenile material. Shoot regeneration was observed after 2–5 months on

selective medium, and transformation efficiency achieved was of about 6%, approximately threefold lower than that obtained for juvenile material. It is probable that aging decreased the susceptibility of plant cells to *Agrobacterium*-infection as well as their organogenic potential. Southern blot analysis confirmed the stable integration of *uidA* and *nptII* gene cassettes into the plants' genome. The putative mature transgenic sweet orange plants showed morphology and growth habits of an adult plant, as compared to control mature plants. In fact, whereas juvenile plants showed a pronounced thorniness, transgenic mature plants were almost thornless, similar to the mature plants from which the explants were taken for transformation. After 14 months in the greenhouse, the transgenic and control plants started to flower, confirming their mature nature (Figure 3a). Both flowers and immature fruits from the transgenic plants showed a dark blue color after overnight incubation in X-Gluc, a substrate of the β -glucuronidase enzyme (Figure 3b). These results confirmed the maintenance of the ontogenic mature stage of the invigorated mature plants as well as the transgenic plants. Interestingly, transgenic events kept their epigenetic mature state even after a process of de-differentiation, induction and redifferentiation, necessary to shift the cells to a competent state for transformation. Therefore, Cervera *et al.* (1998a) directly transformed and regenerated mature tissues of citrus, bypassing the juvenile stage. This process greatly shortens the period of time until flowering and bearing fruits and decreases the time to achieve horticulturally acceptable characteristics by years. Pineapple sweet orange transgenic juvenile plants generated in the same series of experiments needed at least 5 years to start flowering, and 4 years later still keep juvenile characteristics. This transformation procedure for mature citrus tissues has been patented in Spain (no 9700491/X), Europe (no EP 0870838 B1), and United States (no 6.103.955). Moreover, it could be worth trying to apply this transformation and regeneration strategy to transgenic plant production of other woody fruit species with long juvenile periods.

In subsequent experiments, Leandro Peña's group investigated the influence of the components of the feeder plates, namely the TCSs, the filter paper layer, and the TCS culture medium rich in auxins, separately and in combination,

Figure 3 Genetic transformation of mature citrus plants. (a) About 1 year after transformation, regenerated plants started to flower and set fruit, confirming their mature nature. (b) GUS expression in a longitudinal cut from a developing fruit of a transgenic mature sweet orange plant (right) compared to the corresponding nontransgenic control (left)

in the genetic transformation of Mexican lime explants. TCS basal medium was responsible for the increased lime transformation frequency previously attributed to the feeder plates as a whole. The role of the TCSs and the filter paper was even detrimental, as they drastically decreased transformation frequency in comparison with co-cultivation of explants in TCS. Not only was the transformation frequency much higher in explants co-cultivated in TCS, but also the percentage of explants with GUS-positive spots and the maximum number of GUS-positive spots per explant. The liquid layer provided by the cell suspension affected negatively the explants, favoring excessive formation of abnormal callus. On the contrary, the filter paper layer between the basal medium and the explants precluded callus formation at their cut ends (Domínguez *et al.*, 2000). Therefore, TCS was used for co-cultivation in further experiments with Mexican lime and other citrus genotypes. As it was previously shown for Carrizo citrange epicotyl segments (Cervera *et al.*, 1998c), phytohormones (mainly auxins) in TCS seemed to play a crucial role in inducing de-differentiated cells competent for transformation.

The use of vigorous shoots from plants growing in the greenhouse as source of material for

transformation in the case of citrus varieties provides with the possibility of using the same procedure first established to transform juvenile tissues of a given species and also to transform adult materials from the same species (Figure 2). Thus, Leandro Peña's group extended the genetic transformation system for juvenile material to mature citrus tissues of many citrus types of interest, including several sweet orange varieties, sour orange, Mexican lime, Fino lemon, rough lemon, Cleopatra mandarin, and *C. macrophylla* (reviewed in Peña *et al.*, 2004a), and more recently also clementine (Cervera *et al.*, 2008). Alternative to invigoration by grafting, Leandro Peña's group directly used new shoots from the Pineapple sweet orange tree maintained in a screenhouse (at the Germplasm Bank Collection) as starting material for mature transformation (Peña *et al.*, 2004a). Although transgenic plants were generated, the efficiency of the system was much lower (Cervera and Peña, unpublished results). Almeida *et al.* (2003b) used this system with minor modifications to transform mature Hamlin sweet orange with low efficiency. They also used leaf disks from mature plants as explants but poor bud induction and *Agrobacterium* overgrowth even at 1-day co-cultivation impeded transgenic plant recovery. A summary of reports on regeneration of transgenic

citrus plants by organogenesis is shown in Table 1(B).

2.2 Methods Employed for Transformation

2.2.1 Electroporation and PEG-mediated transformation of citrus protoplasts

First reports on genetic transformation of citrus used PEG, electroporation or *A. tumefaciens* as systems for protoplast transformation. Electroporation or addition of PEG to a protoplast suspension induces pore formation in the membranes, so plasmid DNA is able to pass through them and in some cases the DNA becomes integrated in the nuclear genome. Kobayashi and Uchimiya (1989) mixed 10 µg of the circular form of the bacterial plasmid vector carrying the *nptII* selectable marker gene with a protoplast suspension (2.2×10^6) in 0.6 M mannitol. Vardi *et al.* (1990) also used PEG 6000 for protoplast transformation but in this case the plasmid was linearized and calf thymus DNA was used as a carrier. Preliminarily, these authors compared transient transformation mediated either by PEG or by electroporation and found that both the systems worked well, but since the former procedure was simpler and resulted in more consistent transgene transient activity, further stable transformation experiments were PEG-mediated. Electroporation was also attempted by Hidaka and Omura (1993) and conditions were fixed to get transgenic callus colonies. Whereas maximal transgene transient expression was shown in protoplasts electroporated at 1200 V/cm, callus colonies were only formed using voltages between 200 and 600 V/cm. A heat shock treatment at 49 °C before electroporation greatly enhanced transient transformation, as well as using 0.1 mM CaCl_2 in the electroporation buffer. Plasmid DNA concentration of 100 µg/ml and a capacitance of 5.5 µF were also determined as optimal for transient transgene expression.

More recently, PEG-mediated citrus protoplast transformation is being routinely used in J. Grosser's laboratory (Fleming *et al.*, 2000; Olivares-Fuster *et al.*, 2003; Guo *et al.*, 2005), as an extension of their PEG protoplast somatic hybridization method (Grosser and Gmitter, 1990). The protoplast suspension at 2×10^6 cells/ml is aliquoted into 15 ml round-bottomed

tubes at 0.5 ml per tube and 20 µg of plasmid DNA in buffer or water is added to each tube, followed by 0.5 ml of a 40% PEG solution. Niedz *et al.* (2003) optimized electroporation conditions for protoplast transformation. They found that an electric field strength of 375–450 V/cm, a vector DNA concentration of 100 µg/ml, a carrier DNA (salmon sperm DNA) concentration of 100 µg/ml, the use of electroporation buffer at pH 8.0, and preelectroporation heat shock of protoplasts for 5 min at 45 °C, were optimum for DNA uptake into protoplasts as determined by assaying GUS activity 24 h after electroporation. These improvements allowed producing transgenic plants quite efficiently.

2.2.2 *Agrobacterium*-mediated transformation of citrus epicotyl and internodal stem segments

Moore *et al.* (1992) tested Carrizo citrange, Swingle citrumelo, Mexican lime, and Hamlin sweet orange for susceptibility to various *A. tumefaciens* wild-type strains by injecting seedling hypocotyls with bacterial cultures. Although the detailed results of these experiments were not shown, it was clear that all tested citrus types were susceptible to *Agrobacterium* as evidenced by the production of tumors at the wound site following inoculation, and that the succinamopine strain A281 gave rise to very large, rapidly growing tumors. Because of the apparent hypervirulence of its Ti plasmid, pTiBo542, a nononcogenic derivative of this strain, EHA 101, was used in subsequent transformation experiments. Due to the low transformation efficiency achieved, in a second work the same group attempted using the oncogenic strain A518 harboring a binary plasmid with the aim of enhancing transgenic shoot regeneration. GUS-positive shoots were obtained, sometimes at higher frequencies than those obtained with EHA 101, but all of them also contained the oncogenic T-DNA, appearing morphologically abnormal. Therefore, EHA 101 was used in further experiments.

Peña *et al.* (1995a, b, 1997) used *A. tumefaciens* strain EHA 105 for transformation of epicotyl segments from *in vitro*-grown seedlings and of internodal stem segments of greenhouse-grown juvenile plants. EHA 105 is a derivative of EHA

Figure 4 Tumors incited by *Agrobacterium tumefaciens* strains A281, Ach5, and C58 on: (a) Carrizo citrange and (b) Mexican lime. On each photograph, stem marked with CONT corresponds to a mock-inoculated plant. Photographs were taken 28 weeks after inoculation. Three inoculations were performed per stem segment

101 in which the bacterial kanamycin resistance gene from the disarmed Ti plasmid has been removed. Thus, this *Agrobacterium* strain can be used with most binary plasmid systems, as pBin or pCambia vectors, which harbor bacterial resistance to kanamycin. In order to choose a proper *A. tumefaciens* strain for transformation of mature material, we investigated the virulence of three different wild-type strains by inoculating stems of greenhouse-grown sweet orange seedlings. These three strains were A281 (succinamopine type), Ach5 (octopine type), and C58 (nopaline type). *A. tumefaciens* A281 produced the earliest and the highest frequency of tumor formation. Therefore, Leandro Peña's group followed using *A. tumefaciens* EHA 105, a nononcogenic derivative of this strain, as favorite vector for citrus transformation (Cervera *et al.*, 1998b).

To gain more insight on the relationships between *A. tumefaciens* strains and citrus, and to aid in the choice of proper *Agrobacterium* vectors for genetic transformation, Cervera *et al.* (1998b) investigated the virulence of *A. tumefaciens* strain A281, compared to that of Ach5 and C58 on a wide range of agronomically important woody fruit crops. This study included Pineapple sweet orange, Mexican lime, Clemenules clementine, and Carrizo citrange as citrus types. Plants (4–6-month-old) were grown in individual 2.5 l pots and were fertilized weekly. They were kept inside temperature-controlled greenhouses at 24–26/15–16 °C day/night temperatures, with rel-

ative humidity of 60–80%. For each *Agrobacterium* strain and host pair, three inoculations per plant were performed at the same time in all the tested species, at intervals of 5–7 cm and practicing the first wound at 5 cm from the soil. Five microliters of *A. tumefaciens* suspensions in water ($OD_{595} \text{ nm} \approx 0.3$), from 48-h-old cultures, were added to the wounds with a micropipette. The wounds were then covered with plastic wraps for 2 weeks to prevent bacterial desiccation. All the inoculations were performed in April, when plants were actively growing up, and tumor development was allowed to progress for 8–28 weeks. Strain A281 was the most virulent in all citrus types, since it produced earlier appearance and higher tumor formation frequency. On sweet orange and lime, tumor weight was comparable in plants inoculated with strains A281 and C58. However, strain C58 was incapable of inciting tumors in clementine. On citrange, A281 produced earlier-appearing tumors but C58 was as efficient as A281 in tumor formation and incited larger tumors than A281 (Figure 4). Interestingly, tumors induced by strain A281 on the four citrus hosts showed a progressive blackening after 3 months from inoculation. When tumors incited by A281 were excised, 7 months postinoculation, necrosis was severely affecting their morphology and final weight, thus explaining the larger size of tumors produced by strain C58 on citrange, and equivalent sizes of tumors produced by A281 and C58 on sweet orange and Mexican lime. Since tumor necrosis seems to be strongly correlated with

the supervirulent phenotype induced by A281, and this strain incited earlier-appearing tumors and at higher frequencies than the other *Agrobacterium* strains, A281 can be considered supervirulent on the four citrus hosts tested. Strain Ach5 was not effective on sweet orange and clementine, and only produced small tumors at low frequencies on Mexican lime and citrange.

Later, Leandro Peña's group extended this study to other five agronomically important citrus types, Fino lemon, Cleopatra mandarin, *C. macrophylla*, sour orange, and Mediterranean mandarin. Tumors were induced by the three strains in all the genotypes tested, but time of appearance of tumors, tumor frequency, and final tumor weight were clearly different depending on the bacterial strain. A281 was again the most virulent strain, because it induced earlier appearance of tumor and higher tumor formation frequency in most of the hosts, at least until 2 months postinoculation. However, in the cases of Mediterranean and Cleopatra mandarins, C58 was as virulent as A281. Tumors induced by A281 in all the citrus hosts started to become necrotic 2–3 months postinoculation. Such necrosis possibly had a slight effect on final tumor formation frequency, but clearly affected tumor development. Whereas tumors induced by strains Ach5 and, over all, C58 continuously grew until 4 months postinoculation, tumors produced by A281 grew more slowly when necrosis started to affect them. As a consequence, final tumor weight was higher for C58 than for A281 in Cleopatra mandarin and *C. macrophylla*, and similar for C58 and A281 in Mediterranean mandarin. Ach5 incited in general less tumor frequency and weight than the other two strains (Ghorbel and Peña, unpublished results).

Interestingly, the octopine strain LBA 4404, which is a disarmed derivative of Ach5, has been widely used to transform *P. trifoliata* (Kaneyoshi *et al.*, 1994; Kobayashi *et al.* 1996; Kaneyoshi and Kobayashi, 1999; Iwanami *et al.*, 2004; Endo *et al.*, 2005). However, this citrus relative has also been successfully transformed with strain EHA 105 (Wong *et al.*, 2001; Fagoaga *et al.*, 2005), suggesting that it is highly receptive to *Agrobacterium*-mediated gene transfer and that several strains could be used to obtain efficient transformation.

Experiments from Leandro Peña's group clearly indicated that C58 and A281 were appropriate

strains for citrus transformation, A281 being generally much more virulent. A281 is a transconjugant of C58 with pTiBo542 instead of pTiC58, meaning that both strains should interact identically with citrus cells. Therefore, differences in virulence would probably reflect differences in transformation and/or expression of T-DNA and/or *vir* genes. To investigate this, Ghorbel *et al.* (2001b) tested stable transformation in internodal stems segments from Fino lemon, Cleopatra mandarin, *C. macrophylla*, sour orange, and Mediterranean mandarin co-cultivated with the disarmed *Agrobacterium* strains C58 (pMP90) and EHA 105, carrying a binary plasmid (p35SGUSINT) containing *uidA* and *nptII* gene cassettes in the T-DNA. After co-cultivation in the medium rich in auxins that favors transformation (Cervera *et al.*, 1998c), the explants were transferred to a regeneration medium containing kanamycin to allow growth of transformed tissues only. GUS assays were performed 6 weeks after bacterial infections, when T-DNA gene expression was fully stable. For all the citrus genotypes tested, transformation frequency produced by both strains was very different. C58 (pMP90)/ p35SGUSINT produced very low transformation in lime, sour orange, lemon, and *C. macrophylla*, and no transformation in Cleopatra mandarin, while EHA 105/p35SGUSINT produced much higher transformation in all cases, from sixfold in sour orange to 22-fold in lime. Although recovery of transgenic citrus plants was not the main objective of these experiments, transformation frequency provided by EHA 105/p35SGUSINT was so high that we were able to regenerate transgenic shoots from lime, lemon, *C. macrophylla*, and Cleopatra mandarin, just 6 weeks postinoculation. Since the chromosomal background from C58 as well as the T-DNA from p35SGUSINT are identical for the bacterial strains tested, the supertransformation ability of EHA 105/p35SGUSINT in citrus may be attributed to the *vir* region of its Ti plasmid pTiBo542 (Ghorbel *et al.*, 2001b). Consequently, EHA 105 has been the most commonly used *Agrobacterium* strain in citrus transformation.

Bond and Roose (1998) published that C58 was more efficient than EHA 101/105 for transformation of Washington navel sweet orange epicotyl segments. However, EHA 101 and EHA 105 were indistinguishable in their analysis,

being probably very different strains in terms of genetic transformation efficiency in this case, since kanamycin was used as selection marker of transgenic cells being EHA 101 also resistant to kanamycin. Yang *et al.* (2000) also reported that C58 was more efficient than EHA 105 for Rio Red grapefruit transformation, but their experiments were based in transient expression analyses (3 days after co-cultivation) with few explants. More recently, the same group has been using only EHA 105 for transformation of three different grapefruit genotypes including Rio Red (Rai, 2006).

As the supertransformation ability of EHA 105 was attributed to the *vir* region of pTiBo542, Ghorbel *et al.* (2001b) investigated whether supplementary copies of *vir* genes could increase transformation frequency in citrus. The helper plasmid pCH30 (Hamilton *et al.*, 1996) was introduced into C58 (pMP90)/p35SGUSINT and EHA 105/p35SGUSINT. C58 (pMP90) is a disarmed derivative of C58. p35SGUSINT is a binary plasmid carrying *nptII* and *uidA* with an intron, as selectable and reporter marker transgenes, respectively. pCH30 provides additional copies of *virG* from pTiBo542, so this allowed also to investigate the role of this *virG* in the supertransformation ability provided by this Ti plasmid in citrus. Transformation of citrus explants *in vitro* was carried out as described before, and stable transformation was tested 6 weeks after inoculation by performing GUS assays. Two different citrus species were chosen for carrying out these experiments: lime, which was efficiently transformed by EHA 105/p35SGUSINT, and lemon, in which transformation mediated by EHA 105/p35SGUSINT was rather low. C58 (pMP90)/p35SGUSINT produced extremely low transformation frequency in both citrus species. In lime, additional copies of *virG* from pTiBo542 increased transformation frequency induced by C58 (pMP90)/p35SGUSINT about 80-fold, reaching similar transformation frequency than that provided by EHA 105/p35SGUSINT. However, additional copies of *virG* from pTiBo542 in EHA 105/p35SGUSINT did not allow increasing transformation frequency. No further increase in transformation frequency was shown by introducing pCH32 (carrying *virG* and *virE*) instead of pCH30 in any of the two bacterial strains. In lemon, when pCH30 was introduced

into C58 (pMP90)/p35SGUSINT, an increase in transformation frequency of sixfold was obtained, resulting in a transformation frequency similar to that provided by EHA 105/p35SGUSINT, and affording the possibility of regenerating transgenic plants with the use of this strain. Strikingly, pCH30 also enhanced the transformation frequency provided by EHA 105/p35SGUSINT in 1.7-fold. pCH32 provided a similar increase in transformation frequency as pCH30 for both the bacterial strains (Ghorbel *et al.*, 2001b).

VirG is a transcriptional activator that specifically recognizes a 14bp DNA sequence, called the *vir* box, which is found in all *vir* gene promoter regions. The supervirulent phenotype of A281 in its infection to certain hosts has been correlated with higher expression of *vir* genes after induction. Ghorbel *et al.* (2001b) have shown that extra supply of only *virG* from pTiBo542 greatly increased *Agrobacterium*-mediated stable transformation of several citrus genotypes, demonstrating the importance of *vir* induction, and mainly *virG* activation, in the supertransformation ability of this Ti plasmid in citrus. In addition, Ghorbel *et al.* (2001b) have shown that extra copies of this *virG* could complement *vir* induction of pTiC58, providing also to C58 (pMP90)/p35SGUSINT the capacity to supertransform citrus. Looking back to our results on comparison of virulence induced by oncogenic strains in different citrus genotypes, there are genotypes for which C58 is as efficient as A281 for tumor induction, and cases in which A281 incites a too severe reaction at the wounds. In current experiments, Leandro Peña's group is finding citrus types that are severely affected by inoculation and co-cultivation with EHA 105, making very difficult further progress to induce shoot regeneration. For these citrus types, alternative *A. tumefaciens* strains become an almost indispensable need. Using a disarmed derivative of C58 carrying additional copies of *virG* is representing an excellent option in our hands (Peña, unpublished results).

Vir gene inducers, such as acetosyringone, wounded cell extracts, feeder cells, sugars, hormones, wounding, etc. have been extensively used to enhance genetic transformation frequency in many plants. The aim of these treatments was to stimulate *virG* activation and *virA* sensing. Acetosyringone is a phenolic compound produced

during the wounding of plant cells that induces the transcription of the virulence genes of *A. tumefaciens*. Its beneficial role has been demonstrated in the genetic transformation of many plants, including some woody fruit species, as apple (James *et al.*, 1993) and kiwifruit (Janssen and Gardner, 1993). It has being also widely used in citrus transformation, during *Agrobacterium* culture and/or during co-cultivation (Kaneyoshi *et al.*, 1994; Bond and Roose, 1998; Luth and Moore, 1999; Yang *et al.*, 2000; Molinari *et al.*, 2004a), normally at 100–200 μM concentration. However, its role as transformation enhancer was not investigated. Cervera *et al.* (1998c) showed that its addition during co-cultivation increased transformation frequency twofold in Carrizo citrange explants, but when the medium rich in auxins was used for co-cultivation, its effect was not so clear (Cervera *et al.*, unpublished results). Because of this, acetosyringone was not further used in Leandro Peña's lab. More recently, Almeida *et al.* (2003a) used a co-cultivation medium supplemented with acetosyringone at 0, 100, or 200 μM for transformation of epicotyl segments from Rangpur lime and Valencia and Natal sweet oranges. Transgenic shoots were only generated in absence of acetosyringone. It is possible that the effect of acetosyringone in citrus transformation is dependent on the genotype, explant type, and co-cultivation conditions.

2.2.3 *Agrobacterium*-mediated transformation of citrus embryogenic cells and callus

There are a few reports on the use of *A. tumefaciens* as vector for embryogenic callus transformation. Hidaka *et al.* (1990) tested two disarmed *A. tumefaciens* strains and co-cultivation of 3, 5, or 7 days for transformation of cell suspensions coming from embryogenic callus cultures. The bacterial strains were octopine LBA 4404 carrying a binary vector with the *nptII* marker gene, and the nopaline GV3031 harboring a cointegrate vector system with the *hpt* transgene as selectable marker. In general, transformation was very low but 3-day co-cultivation provided a higher number of cell colonies formed with both bacterial vectors. A major problem in the system was that citrus cells were very sensitive to both kanamycin

and hygromycin selective antibiotics, since even concentrations of 10 and 20 mg l^{-1} , inhibited callus proliferation.

Li *et al.* (2002) successfully used the strain EHA 105 for transformation of embryogenic callus from Ponkan by immersion for 25 min in the bacterial culture and 3-day co-cultivation in MT plus 100 μM acetosyringone, in darkness. Transformation conditions were optimized for adapting this procedure to Valencia sweet orange, by preculturing the callus 4 days in MT liquid medium with 0.5 g l^{-1} malt extract, 1.5 g l^{-1} glutamine, and 50 g l^{-1} sucrose. Almost no resistant callus was obtained if the co-cultivation medium lacked acetosyringone.

2.2.4 Less-used transformation systems: *A. rhizogenes* and particle bombardment systems

There is only one report on the use of each of *A. rhizogenes* and particle bombardment systems for citrus transformation. Yao *et al.* (1996) bombarded embryogenic callus cultures of Page tangelo with M-10 tungsten particles coated with plasmid DNA using the Biolistic PDS-1000/HE particle delivery system. Transgenic embryos were produced but most of them were abnormal and conversion to plantlets was generally unsuccessful. Although these results were not satisfactory, Leandro Peña and his co-workers still think that gene bombardment could be a promising transformation system, especially for those explant types that are highly sensitive to *Agrobacterium* inoculation/co-cultivation but have high organogenic/embryogenic potential.

The *A. rhizogenes* A4 agropine-type strain was used for transformation of internodal stem segments of *in vitro*-grown Mexican lime seedlings (Pérez-Molphe and Ochoa-Alejo, 1998). Transformation efficiency achieved was very high, but the aberrant phenotype, the integration of the T-DNA from the Ri plasmid provided to the transformants, has probably precluded its subsequent use for incorporation of transgenes of agricultural interest into citrus types. In spite of this, several authors have proposed the use of *rol* genes from the Ri plasmid as transgenes to produce dwarf *P. trifoliata* and citrange rootstocks (Gentile *et al.*, 1998; Kaneyoshi and Kobayashi, 1999).

2.2.5 Optimizing *A. tumefaciens* and cell/tissue co-cultivation conditions: cell competence for transformation in citrus

As *A. tumefaciens* has been the most commonly used transformation vector for citrus, different research groups have attempted to establish proper infection and co-cultivation conditions with the aim of enhancing transformation frequency. Thus, there are as many protocols on citrus epicotyl segment transformation as laboratories working on this issue. For instance, bacterial inoculation time fluctuates between 5 min (Molinari *et al.*, 2004a) and 20 min (Yang *et al.*, 2000; Almeida *et al.*, 2003a), bacterial concentration for inoculation varies between 4×10^7 (Peña *et al.*, 1995b; Yu *et al.*, 2002) and 5×10^8 (Kaneyoshi *et al.*, 1994; Bond and Roose, 1998; Luth and Moore, 1999), co-cultivation time is usually of 2 or 3 days, and co-cultivation temperature varies between 19 °C (Li *et al.*, 2002, 2003) and 28 °C (Luth and Moore, 1999). Very few papers compare different treatments and then recommend the best conditions for transformation of each citrus genotype, and even less reports investigate why a given treatment is better than others to enhance transformation.

In spite of the high number of studies showing organogenesis and attempting genetic transformation in citrus, little is known about how these two events together contribute to the success of the entire transgenic plant production process. The use of the *uidA* reporter gene allowed

to localize competent cells for transformation in callus presumably formed from the cambium tissue of citrus explants in early steps after co-cultivation with *A. tumefaciens* (Peña *et al.*, 1997; Cervera *et al.*, 1998c). Furthermore, treatments favoring the development of such callus tissue, as co-cultivation in a culture medium rich in auxins and exposure of the explants to darkness during the first 2–4 weeks after bacterial inoculation, greatly increased transformation frequencies and consequently regeneration of transgenic shoots (Cervera *et al.*, 1998c) (Figure 5a). Then, we decided to investigate cell competence and the role of phytohormones for transformation and regeneration of shoots from citrus explants. For this purpose, we used a highly responsive citrus genotype as Carrizo citrange and well-defined tissue culture conditions to perform a histological examination of morphogenesis from citrus explants after co-cultivation with *Agrobacterium* in different culture media: without growth regulators, with BAP at 1 mg l⁻¹, and with 2 mg l⁻¹ 2,4-D, 2 mg l⁻¹ IAA, and 1 mg l⁻¹ 2-iP. Moreover, we used flow cytometry to investigate the role of auxins in the co-cultivation medium as possible enhancers of transformation. Although in all culture media tested regeneration proceeded through indirect organogenesis, co-cultivation in media without phytohormones or with BAP at 1 mg l⁻¹ and subsequent culture in medium with BAP at 3 mg l⁻¹ promoted a faster differentiation response and bud formation. A conspicuous callus was formed from the cambium cells in explants cocultivated in the medium rich in auxins

Figure 5 Histochemical GUS-positive spots in cut ends from transformed epicotyl segments. (a) Computing the average number of GUS-positive events at the cut end of inoculated explants is very useful to determine optimal transformation culture media and conditions. (b) Upper view of the cut end of an explant revealing localization of sites of transgenic GUS expression in callus derived from cambial cells

and bud differentiation did not occur during the first weeks after *Agrobacterium*-inoculation. This is consistent with the totipotent state of cambial cells that were able to rapidly respond to external stimuli during *in vitro* culture. Thus competence for regeneration and cell division were strongly related in citrus epicotyl segments. Interestingly, GUS-assayed explants showed that transgenic sectors were only localized in callus cells coming from the cambium, clearly indicating that the development of the cambial callus was also essential to obtain transformation from citrus explants. Therefore, cells competent for transformation and for regeneration were localized in the same callus tissue.

Flow cytometry analysis revealed that co-cultivation in the medium rich in auxins rapidly favored cell entry into the cell cycle because a higher rate of cells at the cut ends were actively dividing and duplicating their DNA after 2 days of culture in the medium rich in auxins. Thus, addition of auxins to the culture medium promoted active cell division and de-differentiation. This coincided with a much higher transformation frequency in the cut ends of such explants. On the other hand, a lower ratio of S-phase cells was found in the explants during co-cultivation in other culture media, and much lower stable transformation was obtained. Taken together, our data suggest that de-differentiation is crucial for transformation of citrus cells.

Another remarkable observation was that callus from the cambium and therefore stable transformation was preferentially produced at the basal end of the explants, probably reflecting an increase in auxin concentration at the basal ends due to the basipetal auxin transport. Then, it could be hypothesized that citrus cells at the explants would be highly responsive not only to an exogenous auxin supplement but also to endogenous auxin accumulation. Leandro Peña's group results demonstrated that auxins play an essential role in cell competence for transformation in citrus. The promotive effect of phytohormones in shifting cells to a competent state for transformation, especially in the case of auxins is well known. Leandro Peña's group observed that addition of BAP promoted cell division and rapid differentiation of buds, as shown by García-Luis *et al.* (1999), but most of these buds were escapes, indicating that cell

division and callus formation were not enough to ensure efficient transformation. Only buds regenerating later, after more prominent callus formation, were transgenic. Leandro Peña's group results demonstrated that de-differentiation was required to shift citrus cells to a competent state for stable transformation, and that de-differentiation was especially triggered by the addition of auxins (mainly 2,4-D) to the co-cultivation medium and possibly by their endogenous accumulation in specific explant sectors. At the same time, co-cultivation in the medium, rich in auxins, could prevent early differentiation of citrus cells into meristemoids that would result in regeneration of escapes. Once transformation at high frequency was achieved in the proper co-cultivation medium, addition of BAP to the regeneration medium could promote differentiation of the transgenic events into buds and shoots. All these results together indicate that the proper combination of phytohormones in the co-cultivation medium shift the cells at the cut ends of the explants to a competent state for integrative transformation (Peña *et al.*, 2004b). These conclusions have been later extended and applied to the genetic transformation of juvenile and mature internodal stem segments from many different citrus types (Ghorbel *et al.*, 1999; Peña *et al.*, 2004a; Rai, 2006; Peña *et al.*, unpublished results).

2.3 Selection of Transformed Tissue

The *nptII* transgene, conferring resistance to aminoglycoside antibiotics as kanamycin by inhibiting protein synthesis, has been the most widely used selectable marker in citrus transformation and regeneration. However, the first reports on citrus transformation already indicated that kanamycin selection was not working efficiently to regenerate transformants. Vardi *et al.* (1990) showed that kanamycin did not provide a reproducible inhibition curve in Rough lemon protoplast transformation experiments. Therefore, they preferred to use paromomycin, another aminoglycoside antibiotic, over kanamycin, as the selective agent, because it inhibited growth of microcalli at 20 mg l⁻¹. In any case, a few whole plants were generated. Kobayashi and Uchimiya (1989) got transgenic sweet orange microcalli from protoplasts, but these did not develop further by

using kanamycin at 25 mg l^{-1} as selective agent. Hidaka *et al.* (1990) found that embryogenic callus lines from different sweet orange genotypes were highly sensitive to kanamycin and hygromycin even used at low doses.

When internodal stem and epicotyl segments coming from either *in vitro* or greenhouse-grown seedlings were used, kanamycin at 100 mg l^{-1} did not control the regeneration of escapes (Moore *et al.*, 1992; Peña *et al.*, 1995a, b; Gutiérrez *et al.*, 1997). The number of escapes was higher than 90% of the regenerated shoots when the explants were inserted vertically in the culture media (Moore *et al.*, 1992; Peña *et al.*, 1995a; Gutiérrez *et al.*, 1997), but this frequency was strongly reduced (to 45% in Carrizo citrange) when epicotyl segments were disposed horizontally in the media (Peña *et al.*, 1995b). Transformation frequency in etiolated epicotyl segments from *P. trifoliata* was rather high, but even with this species, escapes were produced (16–45%) with kanamycin at 100 mg l^{-1} . When kanamycin concentration was raised to 200 mg l^{-1} , transformation efficiency became lower because high kanamycin dose inhibited the proliferation of transformed as well as untransformed cells (Kaneyoshi *et al.*, 1994). The same effect was shown by Peña *et al.* (1997) in internodal stem segments of Mexican lime and by Cervera *et al.* (1998c) in Carrizo citrange epicotyl segments. The aminoglycoside antibiotic geneticin was also tested at 10 mg l^{-1} as an alternative to kanamycin, but it was toxic for transgenic shoot regeneration in Mexican lime (Peña *et al.*, 1997). Another phenomenon apparently associated to the regeneration of escapes was the production of chimeric shoots at high frequencies, which were likely regenerating from transformed and nontransformed cells (Peña *et al.*, 1995a, b, 1997).

As attempts to raise concentrations of kanamycin and use of alternative aminoglycoside antibiotics failed, utilization of the reporter marker gene *uidA* (or *gus* gene from *Escherichia coli*), present in most transformation vectors used in the 1990s, for shoot screening and selection became the best option to enhance citrus transformation efficiency, because screening revealed transformation more efficiently than lethal selection. In this way, part of all shoots regenerating under a 100 mg l^{-1} kanamycin regime was necessarily screened for histochemical GUS expression, and only the few positive

ones were selected for whole plant production. Therefore, the *uidA* reporter transgene was used as a second selectable marker in most citrus transformation protocols. In addition, *uidA* was instrumental for developing appropriate inoculation, co-cultivation, and regeneration media and conditions. Computing the average number of GUS-positive events at the end of inoculated explants was useful to determine in different genotypes the optimal values for factors affecting transformation (Figure 5a). Moreover, in Leandro Peña's laboratory, *uidA* was very important to localize the sites of transgene expression in citrus explants in order to favor the regeneration of whole plants from such competent cells (Figure 5b) (Peña *et al.*, 1997; Cervera *et al.*, 1998c).

Another major step for the improvement of citrus transformation systems was the employment of the green fluorescent protein gene (*gfp*, from the jellyfish *Aequorea victoria*) as a screenable marker. In contrast to *uidA* and other reporters, the fluorescence emission of GFP only requires excitation of living cells by ultraviolet (UV) or blue light, which results from an internal p-hydroxybenzylideneimidazolinone chromophore generated by an autocatalytic cyclization and oxidation of a Ser-Tyr-Gly sequence at amino acid residues 65–67 (Cody *et al.*, 1993; Heim *et al.*, 1994). It does not require either exogenous substrates or cofactors, thus their applications are not limited by problems in substrates' penetration. Moreover, GFP assays are not destructive, allowing performing *in vivo* monitoring of genetic transformation. Earlier attempts to stably incorporate the wt-*gfp* into citrus protoplasts and plants failed, probably due to the toxicity of the GFP protein to citrus protoplasts (Niedz *et al.*, 1995). In Leandro Peña's laboratory, several different *gfp* gene versions were tested, and the so-called *sgfp* gene provided the most easily identifiable GFP expression in citrus explants. The *sgfp* gene is a re-engineered *gfp* gene sequence with the favored codons of highly expressed human proteins, designed to encode a peptide sequence identical to wild-type protein, combined with the replacement of the serine at position 65 with a threonine. It had given a high GFP expression in maize, tobacco, onion, and *Arabidopsis* cells and in stably transformed tobacco plants (Chiu *et al.*, 1996). Leandro Peña's group first used it for *Agrobacterium*-mediated transformation of epicotyl segments from Carrizo

Figure 6 Use of *gfp* as reporter gene for the localization of competent cells and the recovery of transgenic citrus plants. (a) Green fluorescent cell cluster developed in callus tissue from the cut end of an explant. (b) Upper view of an explant showing a green fluorescent transgenic event at the callus formed from the cambium. (c) GFP expression permits a rapid and easy discrimination of transgenic (green) and escape (red) shoots

citrange and internodal stem segments from Mexican lime and sour orange (Ghorbel *et al.*, 1999). After 1 month in darkness, explants developed callus at the cut ends, which was formed from the cambium tissue. When this callus was examined under a stereomicroscope with 480 nm-excited blue light, it exhibited yellow autofluorescence probably emitted by the walls of de-differentiated cells. In some callus tissue, red autofluorescence cell clusters were also visualized. Since chlorophyll fluoresces red at the wavelength used for GFP excitation, these clusters could be considered nontransformed differentiated cells initiating shoot regeneration. Green fluorescent sectors were also observed that were clearly distinguishable from the red and yellow ones. Green fluorescent cell clusters corresponded to transgenic events (Figure 6a). As each GFP molecule represents one fluorophore, high-level

expression was detected in these cells. Furthermore, continuous monitoring of transformation events led us to observe that they always occurred in callus tissue formed from the cambium in all the three citrus genotypes analyzed. Thus, *in vivo* monitoring of *Agrobacterium*-inoculated plant tissues allowed us to localize competent cells for transformation (Figure 6b).

Mexican lime and citrange shoots started to regenerate from the explants after 1–4 weeks in the light. When they were excited at 480 nm blue light, transgenic shoots showed a bright green fluorescence, whereas escapes and nontransformed control shoots appeared red, again because of the autofluorescence of the chlorophyll. GFP expression permitted a rapid and easy discrimination of transgenic and escape shoots of citrus (Figure 6c). Competition for growth between transformed and nontransformed shoots

could be avoided eliminating the escapes soon after arising. In some cases, Mexican lime and citrange regenerated shoots showed sectorial expression of GFP. These plantlets were derived from transgenic and nontransgenic cells originating from one shoot. Transgenic chimeras could be recognized at a very early stage of development and tissue pattern expression could be followed during the whole life of the plant (Ghorbel *et al.*, 1999).

GFP expression was usually detected in transgenic cells, buds, and shoots, without interfering with the transformation and regeneration of plants. All cells or tissues from leaves of the transgenic plants showed green fluorescence. However, fluorescence intensity varied among different parts of the plant, being higher in new growing leaves than in old ones. In old tissues, lower metabolic activity and chlorophyll accumulation partially masked the green fluorescence provided by GFP. Furthermore, differences in green fluorescence intensity could be observed associated to different GFP expression levels in apical leaves from independent transgenic lines. Therefore, GFP could be used as reporter of gene expression for early nondestructive identification and selection of transgenic buds or shoots expressing the highest levels of protein (Ghorbel *et al.*, 1999).

Efficient monitoring by using GFP for early identification and rescue of transgenic buds could circumvent the use of antibiotic or herbicide marker genes to produce transgenic plants. Interestingly, green fluorescent shoots were regenerated from explants inoculated with *Agrobacterium* but cultured in a medium without kanamycin. These results opened up the possibility to produce transgenic plants without using selective agents. Nontransformed buds could be periodically eliminated to avoid competition with the transgenic ones to favor proper development of shoots only from the transgenic events and thus to increase the frequency of GFP-positive shoots regenerating in a medium without kanamycin selection (Ghorbel *et al.*, 1999). This GFP system has also been used to monitor the process of somatic hybridization through protoplast fusion between a GFP-positive leaf parent and a nontransgenic callus donor, and to successfully localize and select hybrid colonies, callus, embryos, and plants (Olivares-Fuster *et al.*, 2002). GFP-based screening/selection has been widely used for citrus protoplast transformation, since they

seem to be highly sensitive to antibiotics even used at low concentrations. Following protoplast culture in liquid medium and transfer to solid medium, transformed calli could be identified through *in vivo* monitoring of GFP expression, physically separated from nontransformed tissue, and cultured on somatic embryogenesis induction medium (Fleming *et al.*, 2000; Olivares-Fuster *et al.*, 2003; Guo *et al.*, 2005; Niedz *et al.*, 2003).

Even with the use of reporter genes as *uidA* and *gfp* as efficient screenable markers, the number of nontransgenic regenerants and chimeras was high enough to become a problem in most citrus transformation systems. Because of this, we decided to investigate in detail the origin and frequency of escape regenerants in transformation of citrus explants, specifically in Carrizo citrange epicotyl and Mexican lime internodal stem segments. Several possibilities have been proposed to explain the regeneration of escapes: transient expression of the selectable marker transgene in many plant cells during the first transformation steps, selection of mutant plant cells resistant to the selective agent, endogenous nonspecific tolerance of plant cells to the selective agent, protection of the nontransformed cells from the selective agent by the surrounding transformed cells, and persistence of *A. tumefaciens* in infected tissues (Peña *et al.*, 1995b). NPTII accumulation in leaves from 20 randomly selected GUS or GFP-positive plantlets of each genotype ranged from 1100 to 6000 and from 2900 to 9100 ng NPTII/mg total protein in citrange and lime, respectively. No NPTII activity was detected in leaves from control plantlets regenerated from noninoculated explants cultured in regeneration medium without kanamycin. Taken together the lack of escapes from noninoculated explants cultured in selection medium, and the absence of endogenous NPTII activity in nontransformed regenerated control shoots, the hypothesis of endogenous nonspecific tolerance of citrus cells to kanamycin to explain the regeneration of escapes and chimeric shoots can be discarded (Dominguez *et al.*, 2004).

To investigate the origin of GUS and GFP-negative/chimeric regenerants, citrange and lime explants were analyzed for GUS expression with the histochemical GUS assay, and for GFP expression under blue light, respectively, from a few weeks to 5 months after infection, when most shoots had already arose. In citrange, most

GUS-negative/chimeric shoots regenerated close to or even from GUS-positive spots. In lime also, a very high rate of GFP-negative/chimeric regenerants was observed coming from GFP-positive transgenic events. This strongly suggested that protection of nontransformed cells from kanamycin by the surrounding transformed cells accounted for most of the escapes and chimeric shoots generated in both citrus genotypes. In fact, detailed observation of certain prominent transgenic events allowed us to observe that in many cases they were composed of mixtures of GUS or GFP-positive and GUS or GFP-negative cells. However, a considerable number of GUS and GFP-negative/chimeric regenerants arose from cut ends without any transgenic event indicating that factors other than protection of escapes by close transgenic cells should also be considered (Domínguez *et al.*, 2004). It has been proposed that transient expression of the selectable marker transgene in many plant cells could play an important role in generation of this type of nontransgenic shoots during genetic transformation of tobacco leaf disks (Park *et al.*, 1998). However, this is unlikely to occur in citrus because shoot regeneration is slow, starting from 1 month after co-cultivation.

Then Leandro Peña's group tested persistence of *Agrobacterium* in citrus explants. Nine months after co-cultivation, lime explants were subcultured to selection medium without cefotaxime and vancomycin for 3 months. During this time, 80–90% of the explants became contaminated by *Agrobacterium* overgrowth, as confirmed by polymerase chain reaction (PCR) analysis of the agrobacterial-like colonies. The remaining explants were analyzed for the presence of the bacteria at the cut ends by culture of basal sections in selective media and subsequent PCR for identification. In two experiments, still 49% and 12.5% of the explants cultured in selective medium contained persisting *Agrobacterium* cells. Interestingly, these frequencies reached 65% and 45% when the explants were cultured in enriched selective medium, indicating that a more sensitive analysis revealed a higher frequency of bacterial detection in the explants. Moreover, these frequencies could be even higher because nonculturable *Agrobacterium* cannot be detected using this method. After co-cultivation, citrus explants are transferred to a regeneration/selection

medium containing the antibiotics cefotaxime and vancomycin to control *Agrobacterium* overgrowth. However, complete elimination of the bacteria seemed to be difficult mainly because the antibiotics used are bacteriostatic rather than bactericidal. It is also possible that resistance of the engineered *Agrobacterium* strains used to kanamycin could provide a selective advantage to bacterial cells over nontransformed plant cells and tissues in the *in vitro* culture medium. In any case, it is clear that the consistent presence of bacterial colonies resistant to kanamycin in certain tissues at the cut ends of the explants could detoxify the surrounding nontransgenic tissues and favor the regeneration of escapes. This could especially explain the regeneration of escapes in cut ends without any transformation event (Domínguez *et al.*, 2004).

In addition, Southern blot characterization of individual propagations from GUS-positive shoots revealed that 12% were actually chimeras from either transgenic and nontransgenic events or from different transformation events, indicating that chimeric shoots resulted not only from the convergence of transgenic and nontransgenic cells as shown by reporter gene expression, but also from the union of different transgenic events (Domínguez *et al.*, 2004).

These facts have important implications in the production of transgenic citrus plants. With the aim of preventing the generation of escapes and chimeras, strategies directed to avoid *Agrobacterium* persistence in plant tissues, and the use of alternative, preferably antibiotic-free positive selection marker genes that could not be expressed in the bacteria would be advisable. The use of alternative selective agents has been attempted. Li *et al.* (2002) used the phosphinothricin acetyl transferase (PAT) *bar* gene, providing resistance to glufosinate ammonium (active ingredient of the BASTA[®] herbicide), to transform Ponkan calli with *A. tumefaciens* and efficiently regenerate whole plants through somatic embryogenesis in culture media supplemented with Basta at 50 mg l⁻¹. Few escapes and no chimeras were generated with this transformation system. One year later, the same group (Li *et al.*, 2003) also used the *hpt* gene, providing resistance to the antibiotic hygromycin, as selection marker gene for developing successful *Agrobacterium*-mediated embryogenic callus transformation of

Valencia sweet orange. We have tested both *bar* and *hpt* as selectable markers for epicotyl and internodal stem segment transformation of several citrus genotypes. Initial regeneration experiments were performed in order to choose the appropriate hygromycin and basta concentrations to control regeneration from nontransformed explants. In the case of hygromycin, regeneration was impeded from a concentration of 10 mg l^{-1} in Carrizo citrange epicotyl segments. A slight toxicity was, however, noticed at this and at lower concentrations, causing developmental anomalies in regenerated shoots. Results from tests using bialaphos as regeneration-controlling agent indicated that a concentration of 5 mg l^{-1} was appropriate for citrus transformation. In transformation experiments, the use of any of both selective agents allowed to produce transgenic plants (Cervera *et al.*, 2006; Cervera *et al.*, unpublished results).

Most of the selectable markers genes used to date, including *nptII*, *bar*, and *hpt*, are based on the addition to the culture media of a substance that is toxic to untransformed cells. There is a concern that the transformation efficiencies are suboptimal with toxic substrates because dying untransformed cells may inhibit transformed cells from proliferating by secreting inhibitors or preventing transport of essential nutrients to the living transformed cells (Haldrup *et al.*, 1998). Alternatively, the *manA* gene, which codes for phosphomannose isomerase (PMI), is an example of a conditional-positive selection system where the selection substrate is not toxic. In this system, the substrate mannose is unable to act as a carbon source for untransformed cells but it will promote the growth of cells transformed with *manA*. This system has been used for sweet orange transformation from epicotyl segments (Boscardi *et al.*, 2003). Mannose used as the sole carbon source, at 73–112.3 mM concentrations depending on the genotype, promoted transgenic shoot regeneration. Transformation efficiency achieved varied between 3% and almost 24%, but escape regeneration was not avoided and about 57% of the total regenerants were not transgenic.

Nonconditional positive selection systems do not require external substrates, yet promote the selective growth and differentiation of transformed material. An example is the isopentenyl transferase gene (*ipt*) from *A. tumefaciens*, which catalyzes the

production of a precursor of several cytokinins that enhance shoot development by modifying the plant hormone levels endogenously. Leandro Peña's group have used this system in citrus transformation and compared it with *nptII* selection. An important characteristic of *ipt* used as positive selectable marker in genetic transformation of citrus was that *ipt* overexpression was sufficient to promote shoot organogenesis in citrus (Figure 7). Regeneration was comparable to that obtained by supplementing a cytokinin (BAP) to the regeneration medium. Moreover, *ipt* was a reliable positive selectable marker that permitted to select transgenic sweet orange shoots from internodal stem segments at the first stages of development, since they showed a clearly distinctive phenotype. In citrange epicotyl segments, *ipt* overexpression induced adverse pleiotropic effects in the explants and their regenerants, and transgenic selection was only possible after PCR analysis of the *ipt* transgene in the regenerated shoots or plantlets. These results suggest that citrange cells are highly sensitive to IPT accumulation, likely causing hormonal imbalances detrimental for development. Compared to kanamycin selection, the *ipt* system permitted to increase transformation efficiency in sweet orange about three times, but was much less efficient in Carrizo citrange (Ballester *et al.*, 2007). Due to the induction of significant alterations in the morphology, development, and physiology of the transgenic plants, this marker had to be combined with a site-specific recombination and DNA removal system to generate *ipt*-free plants (Ebinuma *et al.*, 1997; Sugita *et al.*, 1999).

2.4 Regeneration of Whole Plants

For regeneration of whole transgenic citrus plants through organogenesis and somatic embryogenesis, tissue culture media and conditions are similar to those fully established for several other biotechnological applications. However, these media are usually supplemented with antibiotics, which are toxic to most cells/tissues in culture, since only a few cells of those put in contact with the vector become transformed. In addition, gene transfer itself provokes important alterations in transformed cells and regenerated shoots or embryos. Therefore, the ideal regeneration medium should facilitate the development of

Figure 7 Isopentenyl transferase gene (*ipt*) as positive selectable marker in genetic transformation of citrus. *ipt* overexpression is sufficient to promote shoot organogenesis in citrus. Different phenotypes are exhibited by *ipt*-positive (a) and *ipt*-negative (b) Pineapple sweet orange shoots

buds or microcalli from transgenic cells, and at the same time avoid the generation of escapes. As escape regeneration is a major obstacle in all citrus transformation systems and with all marker genes tested to date, regeneration media and conditions have been adapted to favor the growth and development of transgenic events. Peña *et al.* (1995a, b, 1997) proposed the cultivation of explant in darkness for 2–4 weeks in regeneration/selection medium after co-cultivation with *A. tumefaciens*. This enhanced not only transformation frequency, but also promoted the generation of large transgenic events able to regenerate whole transformed buds (Domínguez *et al.*, 2004; Peña *et al.*, 2004b). Its beneficial role for citrus explant transformation has been demonstrated in several laboratories (Cervera *et al.*, 1998c; Yu *et al.*, 2002; Almeida *et al.*, 2003b; Boscardioli *et al.*, 2006). For some genotypes and in general for mature tissue transformation, the addition of NAA at different concentrations to the regeneration medium during cultivation in darkness strongly promoted the development of the transgenic events (Ghorbel *et al.*, 2000; Almeida *et al.*, 2003b; Rodríguez *et al.*, 2008). Molinari *et al.* (2004a) suggested that transfer

of the explants after *Agrobacterium* co-cultivation to a medium without selective agent for a week, followed by 25 mg l⁻¹ kanamycin for 3 weeks, and then to 50 mg l⁻¹ kanamycin was optimal for regeneration of transgenic Swingle citrumelo plants from thin layer explants.

The most important problem of whole transgenic plant production in citrus has been the extraordinary difficulty found in rooting transgenic shoots and embryos, which seriously reduces transformation efficiencies. Probably, the only exceptions are *P. trifoliata*, grapefruit, and Swingle citrumelo, which could be rooted in MS supplemented with NAA (Kaneyoshi *et al.*, 1994; Luth and Moore, 1999; Molinari *et al.*, 2004a).

As an alternative method for the generation of whole transgenic plants, shoot tip grafting (Navarro *et al.*, 1975) was introduced by the procedure of Peña *et al.* (1995a, b). Small pieces of the shoots emerging from the explants were assayed for reporter marker activity and, when the result was positive, apical portions were grafted *in vitro* onto Troyer citrange seedlings. Rootstock preparation was as follows: Troyer citrange (or any other rootstock) seeds were peeled removing both

Figure 8 Apical portions from transgenic regenerated shoots are grafted *in vitro* on citrange seedlings. Regenerated shoot apical ends are placed on the top cut surfaces of the decapitated citrange epicotyls, in contact with the vascular ring, or, when larger than 0.4 cm, they are inserted into a vertical incision along the length of the epicotyl, starting at the point of decapitation (a) or in a lateral incision (b)

seed coats, disinfected for 10 min in a 0.5% sodium hypochlorite solution containing 0.1% Tween-20 and rinsed three times with sterile water. The germination medium was MS salts with 10 g l⁻¹ agar, pH 5.7. Seeds were sown individually in tubes and grown in dark at 27 °C for 2 weeks. Troyer citrange seedlings were decapitated leaving 1–1.5 cm of the epicotyls. The roots were shortened to 4–6 cm and the cotyledons and their axillary buds were removed. Then, the regenerated shoot apical ends were placed on the top cut surfaces of the decapitated citrange epicotyls, in contact with the vascular ring, or when larger than 0.4 cm, they were inserted into a lateral incision or in a vertical incision along the length of the epicotyl, starting at the point of decapitation (Figure 8). Grafted plants were cultured in a liquid medium composed of MS salts, 100 mg l⁻¹ m-inositol, 0.2 mg l⁻¹ thiamine-HCl, 1 mg l⁻¹ pyridoxine-HCl, 1 mg l⁻¹ nicotinic acid, 75 g l⁻¹ sucrose, pH 5.7. The cultures were kept at 25 °C, 16 h of photoperiod, 45 µE m⁻² s⁻¹ of illumination. Shoots with only 0.1 cm in length could be used to regenerate transgenic plants following this protocol. A frequency of 100% successful grafts is usually obtained. Scions develop two to four expanded leaves, 3–4 weeks

after grafting. A new grafting of the *in vitro*-grown plants on vigorous rootstocks in the greenhouse allows the rapid acclimatization and development of the plants. Grafted plants are kept in a shadow area and are covered with a closed plastic bag for about 1 month. Then the bag is progressively opened, and when the shoot starts to actively grow, plant is transferred to a greenhouse area with normal illumination. This system is routinely used in our laboratory and has permitted to recover whole transgenic plants from all citrus types tested, even in cases in which the transgene of interest induced malformations in the regenerated shoots (Fagoaga *et al.*, 2005).

The grafting system has been demonstrated to be reliable and widely applicable for whole plant production also in other laboratories and for many different citrus genotypes, including *P. trifoliata* and grapefruit (Kobayashi *et al.*, 1996; Bond and Roose, 1998; Gentile *et al.*, 1998; LaMalfa *et al.*, 2000; Wong *et al.*, 2001; Mendes *et al.*, 2002; Yu *et al.*, 2002; Almeida *et al.*, 2003a, b; Boscariol *et al.*, 2003; Iwanami *et al.*, 2004; Endo *et al.*, 2005). It has been mostly used to recover whole plants from shoots regenerated through organogenesis, but also to regenerate plants from germinated

somatic embryos (Fleming *et al.*, 2000; Olivares-Fuster *et al.*, 2003; Guo *et al.*, 2005; Niedz *et al.*, 2003). Moreover, this method could be applied to the recovery of transgenic plants from other woody plants, in which shoots are difficult to elongate and/or root, and escapes regenerate at high frequencies competing with the transgenic shoots.

Alternatively, for certain purposes, rooting of the transgenic shoots allow performing rapid analyses of the effect of the transgene of potential interest even *in vitro* when the new inserted trait could affect not only to the aerial part of the plant but also the roots (i.e., higher tolerance to salinity, modification of plant size or architecture, etc.). Although development of whole plants is slower and less efficient than performing *in vitro* grafting, rooting can be obtained by cutting 0.5–1 cm regenerated shoots from the explants and transferring them to SRM supplemented with 0.3 mg l⁻¹ BAP for 7–10 days, and then to SRM medium supplement with 5 mg l⁻¹ indolebutyric acid. At least for Mexican lime and Fino lemon, roots develop within a 3–6 weeks period with 90–100% efficiency (Peña, unpublished results).

2.5 Incorporation of Transgenes of Interest Into Citrus

Although there are many reports on introduction of transgenes of potential interest into citrus, few of them describe how the expression of the transgene affects the phenotype of the modified rootstock or variety genotype. This is due in part to the low number of transgenic plants generated in some cases, to the fact that juvenile tissues were transformed in most cases and consequently fruit characteristics could not be evaluated yet, and also due to the difficulties of performing challenge assays against pathogens with woody plants.

In the first attempts to transform citrus, only marker genes as the selectable marker *nptII* and the reporter marker *uidA* were used. Moreover, constitutively expressed promoter and terminator sequences, as those from the 35S gene of *Cauliflower mosaic virus* (CaMV) or from the nopaline synthase (*NOS*) gene of *A. tumefaciens*, were predominantly used. Availability of a genetic transformation system for *P. trifoliata* (Kaneyoshi *et al.*, 1994) allowed to efficiently incorporate

the human epidermal growth factor (hEGF) (Kobayashi *et al.*, 1996) and the *rolC* gene from *A. rhizogenes* (Kaneyoshi and Kobayashi, 1999) into this species. In their first paper, Kaneyoshi *et al.* (1994) used the *uidA* gene under the control of the 35S promoter, and under the control of the promoter from the *rolC* gene. As expected, the 35S promoter directed GUS expression in all leaf, stem, and root tissues of the transgenic regenerants. Interestingly, histochemical GUS expression was only detected in phloem cells when the *rolC* promoter was used. As the precise role of hEGF *in vivo* was unknown, the work of Kobayashi *et al.* (1996) only served to demonstrate that it was possible to express human bioactive peptides in transgenic trees. Eleven plantlets were obtained from 282 treated segments (4% transformation efficiency), and seven were regenerated into whole plants by grafting. The highest hEGF achieved was 113 pg mg⁻¹, which was considered low.

2.5.1 Tree performance

The following report by Kaneyoshi and Kobayashi (1999) was more interesting from an agricultural point of view since its purpose was to produce dwarf rootstocks able to impart dwarfism to the scion. The *rolC* gene was used for this purpose under the control of either the 35S promoter or its own promoter. Transgenic plants were produced with both constructs at high efficiency. Most transgenic lines were dwarf, and the degree of dwarfism differed among lines; 35S::*rolC* transformants were 40% shorter than controls, while *rolC*::*rolC* lines ranged from 10% to 120% shortenings. Six transformants (three from each group) were assayed for rooting of cuttings. Five of them rooted better and one *rolC*::*rolC* line (with the longest internodes) rooted similarly to controls. As next step, Kaneyoshi and Kobayashi (1999) planned to graft some citrus cultivars onto the transgenic plants and check their potential as dwarfing rootstocks, but no report has been published to date on this aspect. Gentile *et al.* (1998) regenerated transgenic plants of Tarocco sweet orange and Carrizo citrange with *rolABC* genes from *A. rhizogenes*. Although plant phenotypes were not characterized in detail, preliminary observations indicated that they grew with difficulties and

showed morphological anomalies, as small and narrow leaves.

Fagoaga *et al.* (2007) have produced transgenic Carrizo citrange plants overexpressing a citrus gibberellin (GA) 20-oxidase cDNA (*CcGA20ox1*) in sense or antisense under the control of the 35S promoter to modify plant architecture. *CcGA20ox1* is a key enzyme of gibberellin biosynthesis. Expression of the transgenes was assayed by Northern blot and Western blot analyses in both antisense and sense transgenic lines. In sense transgenic lines, the level of *CcGA20ox1* protein was high and correlated with plant height and internode length. The leaf area was considerably smaller than that of the control plants. In antisense transgenic lines, down-regulation of *CcGA20ox1* resulted in both shorter internodes and dwarfing with larger number of branches. No adverse pleiotropic phenotypic effects were observed in these plants. As expected, taller (sense) and shorter (antisense) phenotypes correlated with higher and lower levels, respectively, of active GA1 in growing shoots of the transgenic plants (Fagoaga *et al.*, 2007). We are currently investigating whether antisense transgenic Carrizo citrange used as rootstock is able to reduce the size of nontransgenic scions. Potential reduction of scion plant stature by down-regulating GA20ox of a well known and widely used rootstock would provide a considerable benefit to citriculture by allowing higher planting density, easier management and fruit harvesting, thus reducing labor costs.

2.5.2 Higher tolerance to abiotic stresses

Soil salinity significantly limits citrus production in several areas worldwide. Carrizo citrange, considered an excellent citrus rootstock, is very sensitive to salt stress, which restrains its use in salty soils. We have successfully transformed plants of Carrizo citrange with the halotolerance gene *HAL2* under control of 35S promoter (Cervera *et al.*, 2000a). This gene was originally isolated from yeast and is implicated in salt tolerance mechanisms (Murguía *et al.*, 1995). Plants showing higher transcription levels in Northern blot analyses were chosen to accomplish *in vivo* salt stress tolerance assays, by using transgenic plants as rootstocks for a sensitive citrus

variety. However, transgenic lines did not show higher tolerance to salinity than controls.

The accumulation of proline represents a general response to stress in many organisms, including higher plants, exposed to environmental stresses such as water deficit, high salinity, high temperature, freezing, UV radiation, and heavy metals. Molinari *et al.* (2004b) have incorporated a Δ^1 -pyrroline-5-carboxylate synthetase mutant gene (*P5CS*) from *Vigna aconitifolia* driven by the 35S promoter into Carrizo citrange plants, with the objective of increasing proline accumulation in all tissues and consequently enhancing tolerance to drought stress. In well-watered conditions, transgenic plants accumulated proline in leaves up to eightfold higher than in control plants. As compared to controls of the same age, no apparent differences in growth and morphology were observed in the transgenic Carrizo citrange plants after 5 months in the greenhouse. Ten days after water had been withheld, when water present in substrate was not available to the plant, there was an accentuated fall in photosynthetic rate and increase in the values of stomatal resistance in nontransgenic plants, while the transgenic plants showed comparatively minor changes in these two parameters. The values of stomatal resistance and transpiration during the experiment period showed that transgenic plants were able to support the applied water deficit stress. The adoption of well-established citrus rootstocks with enhanced drought tolerance could represent a promising strategy in maintaining productivity in citrus-growing regions with water deficit.

2.5.3 Rapid cycling citrus trees

Results of genetic improvement programs for citrus are very limited, due, among other reasons, to the extremely long juvenile phases of the trees, which prolong the time required to analyse late traits like fruit features. With the aim to accelerate their flowering time, we have transformed juvenile Carrizo citrange seedlings to constitutively express the *Arabidopsis* *LEAFY* (*LFY*) or *APETALA1* (*API*) genes that are sufficient to promote flower initiation in *Arabidopsis* (Mandel and Yanofsky, 1995; Weigel and Nilsson, 1995). Chimeric genes with their coding regions fused to the 35S promoter were used. Expression of the 35S::*LFY* and

Figure 9 Overexpression of *APETALAI* from *Arabidopsis* in Carrizo citrange transgenic plants induces an early flowering phenotype. Transgenic *APETALAI* plants flowering 6 months after sowing (four plants on the right) compared to a nontransformed control plant (plant on the left)

35S::*API* transgenes was confirmed by Northern blot hybridization. In contrast to the development of regenerated nontransformed control plants, most of the 35S::*LFY* transgenic trees developed thin stems with a weeping growth habit and with a rapid reduction in the number and size of thorns. Leaf size was also reduced, and leaves displayed a variable degree of curling in different transgenic lines. The most extreme phenotypes were observed in transgenic plants showing a higher level of accumulation of *LFY* transcript in leaves. Flowering time was strongly accelerated in many of those plants, which initiated flowering in spring, 12–20 months after their transfer to the greenhouse. Transgenic trees carrying the 35S::*API* construction displayed more normal growth than the 35S::*LFY* trees. Many plants showed rapid signs of phase change, evidenced by the reduction in the size and number of thorns. Furthermore, leaves displayed heart-shaped leaflets, typical of adult citrange trees (Peña *et al.*, 2001).

Both types of transgenic citrus plants produced fertile flowers and fruits as earlier as the first year, notably through a mechanism involving a dramatic shortening of their juvenile phase. Furthermore,

expression of *API*, being as efficient as *LFY* in the initiation of flowers, did not produce any severe developmental abnormality. Both types of transgenic trees flowered again in consecutive years and their flowering response was under environmental control (Figure 9). In addition, sexual and nucellar-derived transgenic seedlings had a very short juvenile phase and flowered in their first spring, demonstrating the stability and inheritance of this trait (Peña *et al.*, 2001). This opens the possibility to use independent *API* transgenic plants as parents in crosses with nontransformed genotypes that would yield 50% of the progeny flowering and setting fruits in 1–2 years, thus providing the opportunity to evaluate fruit features very early and to rapidly advance generations. On the other hand, by retransformation of *API* transgenic citrus plants it could be possible to rapidly test the effect of the expression of certain transgenes under flower organ or fruit specific promoters as a system to look for biotechnological strategies to develop seedless varieties, modify fruit color and aroma, or favor easy-peeling characteristics. Retransformation of *API* Carrizo citrange plants has been successfully achieved in Leandro Peña's

laboratory (Cervera *et al.*, 2006). In addition, the 35S::*API* construction has been incorporated into other *Citrus* genotypes and it also promoted early flowering and fruiting features (Cervera *et al.*, unpublished results).

FLOWERING LOCUS T (FT) is another flowering time gene of *Arabidopsis* and is characterized as a floral pathway integrator. An *FT* homolog (*CiFT*) was found in the expressed sequence tag catalog of a cDNA library from the fruit of satsuma mandarin and its overexpression induced an early flowering phenotype in *Arabidopsis*. Endo *et al.* (2005) introduced *CiFT* under the control of the 35S promoter into *P. trifoliata* and generated transgenic plants that flowered in general in less than 8 months. Four out of six transgenic lines developed normal fruits with intact seeds. All lines of the 35S::*CiFT* plants had a leafy inflorescence architecture, in which flowers and leaves concurrently developed. In contrast, wild-type *P. trifoliata* plants usually develop solitary flowers in the axils of leaves. Differentiation of floral buds starts in early summer and is completed prior to the onset of winter dormancy. In the transgenic plants, the development of flowers was not interrupted by a dormant period. The tree shape of transgenic plants was dwarfed and branched in comparison with that of the controls, and the leaf shape was morphologically altered. Moreover, the leafy inflorescence was often accompanied with gradual changes of thorns into flowers. Nucellar and sexual progeny seedlings from these lines showed extremely early flowering, developing floral buds almost immediately after germination. Although *CiFT* induced many pleiotropic effects on plant growth and development, early flowering *CiFT-P. trifoliata* plants could be a helpful tool for functional genomics studies in citrus. It could be also very interesting to verify the effect of 35S::*CiFT* in *Citrus* genotypes.

2.5.4 Improvement of fruit quality

Li *et al.* (2002, 2003) reported the generation of Ponkan and Valencia sweet orange transgenic plants, respectively, through *Agrobacterium*-mediated transformation of embryogenic calli with a chimeric ribonuclease gene (*barnase*) derived from *Bacillus amyloliquefaciens* under the control

of an anther tapetum-specific promoter (pTA29). The aim of the work was to produce pollen sterile transformants, and subsequently seedless fruit. More than 20 lines from each genotype were generated. Since transformants were juvenile, several years of cultivation are needed to evaluate possible male sterility. The same can be applied in part for Koltunow *et al.* (2000) who produced juvenile transgenic Mexican limes containing genes for decreased seed set. However, the juvenile period of Mexican lime is one of the shortest among citrus types. In spite of it, to our knowledge there are no published data on the phenotype of the mature plants and their fruits.

Costa *et al.* (2002) introduced several carotenoid biosynthetic genes under the control of constitutively expressed promoters into juvenile Duncan grapefruit (*see* Grapefruit for description of this work). Wong *et al.* (2001) introduced a 1-aminocyclopropane-1-carboxylate synthase gene (*CS-ACS1*) isolated from *C. sinensis* under the control of a double 35S promoter into *P. trifoliata* and Carrizo citrange seedlings in antisense orientation. Eight and 13 Southern blot-positive plants were generated, respectively. Two and seven of these plants, respectively, expressed the antisense messenger-RNA (mRNA) at detectable levels. Those transgenic lines producing higher levels of antisense mRNA were found to partially repress the increase of ACC accumulation after a chilling treatment. The authors speculated that the reduced level of ACC in transgenic citrus tissues following the chilling treatment could be useful to reduce the damages caused by chilling injury in citrus fruits. However, several years are needed to get mature plants producing enough number of transgenic fruits.

Guo *et al.* (2005) introduced a pectin methylesterase gene (*Cs-PME4*) isolated from sweet orange into Valencia sweet orange protoplasts. *Cs-PME4* cDNA was cloned in sense between a double 35S promoter and a *gfp* (*e-gfp*) marker gene, so the promoter was controlling the expression of both cistrons. Several transgenic plants were recovered but all of them came from the same transformation event. In addition, the plants exhibited a slightly abnormal morphology, likely attributable to the *gfp* version used. Transgenic plants were juvenile and require years to flower and fruit. Then, it will be possible to investigate whether *Cs-PME4* overaccumulation

occurs in fruit cells. From a biotechnological perspective, it would be interesting to down-regulate *Cs-PME4* with the aim of preventing juice cloud separation.

2.5.5 Resistance to pathogens

Phytophthora citrophthora is the most widely spread oomycete all over the citrus-growing areas and represents one of the major causes of crop losses. Constitutive overexpression of proteins involved in plant defense mechanisms is one of the strategies proposed to increase plant tolerance to fungal pathogens. P23 is a 23-kDa pathogenesis-related protein induced in tomato (*Lycopersicon esculentum* Mill. cv. Rutgers) plants when these are infected with citrus exocortis viroid and its antifungal activity has been shown in *in vitro* assays (Rodrigo *et al.*, 1993). Fagoaga *et al.* (2001) have successfully produced transgenic Pineapple sweet orange plants with a chimeric gene construct comprising the coding region of the *P23* gene under the control of the 35S promoter. Nine transgenic lines accumulated the P23 protein, as determined in Western blot analyses, and in general P23 accumulation levels were high in most lines. Transgenic lines constitutively expressing the *P23* transgene were challenged with *P. citrophthora* by using detached bark and whole plant assays. One of them achieved consistently reduced susceptibility in both assays. This line showed plant survival rates higher than the control when whole transgenic plants were inoculated with fungal cultures, since only one of 10 inoculated plants died at the end of the 2-year assay, while 50% of the controls have died 6 months after inoculation. The exact nature of tolerance to *P. citrophthora* provided by constitutive tomato *P23* (PR-5) expression in transgenic orange plants is unknown. These results provide evidence for the antifungal activity *in vivo* of the P23 pathogenesis-related protein against *P. citrophthora* and suggest that this may be employed as a strategy aimed at the engineering of *Phytophthora* disease resistance in citrus (Fagoaga *et al.*, 2001).

CTV is the causal agent of the most important virus disease of citrus in the world. It produces two main field syndromes: common strains cause decline and death of most scion varieties grafted on sour orange rootstock, whereas highly virulent

strains additionally cause stem pitting, stunting, low yield, and poor fruit quality of some varieties of sweet orange, limes, and grapefruits, regardless of the rootstock used. Several strategies have been used to engineer plant resistance to viral pathogens. Most are based on the concept of pathogen-derived resistance (PDR), which proposes that the introduction and expression in plants of viral sequences could interfere with the life cycle of the same or a closely related challenging virus, thus providing resistance to infection. Gutiérrez *et al.* (1997) produced a few transgenic plants of sour orange, Mexican lime, and Carrizo citrange with the *p25* major coat protein gene from CTV. However, challenge analysis of these plants has not been reported to date.

Domínguez *et al.* (2002c) generated more than 40 transgenic Mexican lime lines, 25 containing the *p25* gene from the severe CTV strain T305, and 17 from the mild strain T317. Transgene integration patterns were usually complex, with almost half of the plants showing T-DNA truncations and a copy number of the *p25* transgene ranging from one to six. Accumulation of *p25* was detected in most of the transgenic lines (Domínguez *et al.*, 2000). When 8–10 propagations of each transgenic line were graft- and aphid-inoculated with CTV isolates T305 and T300, respectively, two types of responses to viral challenge were observed: most lines developed CTV symptoms similar to those of the nontransgenic controls, but six of them exhibited resistance against the virus. This consisted of a fraction of plants, ranging from 10% to 33%, that were immune to CTV, with the rest showing a significant delay in virus accumulation and symptom onset in at least three consecutive flushes (about 1 year) after inoculation (Domínguez *et al.*, 2002c). These results were reproduced with four of the six transgenic lines in an additional challenge experiments in which propagations were again graft-inoculated with CTV T305: three *p25* resistant lines accumulated *p25* at high levels, suggesting that a protein-mediated resistance mechanism was operative in these lines, whereas the fourth transgenic line, called SCP.15, showed almost undetectable *p25* accumulation and consistent resistance. Moreover, this line exhibited silencing of the *uidA* transgene, used as reporter in the T-DNA of the transformation vector, as determined by the lack of histochemical GUS expression in leaf pieces. Post-transcriptional

gene silencing (PTGS) of the *uidA* transgene was confirmed in Northern blot hybridization and nuclear run-on analyses (Domínguez *et al.*, 2002a; Domínguez and Peña, unpublished results). When eight plants propagated from the SCP.15 line were graft-inoculated with CTV T305, two were immune to virus challenge and the *uidA* transgene remained silenced in their leaves along the 1-year-duration of the experiment, but the other six plants became direct antibody sandwich-enzyme-linked immunosorbent assay (DAS-ELISA) positive for CTV and started showing symptoms at the second or third flush postinoculation. Interestingly, infection of these plants was directly related with activation of GUS expression, indicating that CTV might encode a suppressor of gene silencing which could restore GUS expression in infected transgenic plants carrying the *uidA* silenced. This result also suggested that PTGS of the *p25* transgene was involved in the propagations that remained immune to CTV. This was the first demonstration of PDR against a member of the genus *Closterovirus* in its natural host. In the frame of a collaboration project of the IVIA with the University of Hawaii (M. Melzer, S. Ferreira, and J. Hu) and the USDA (D. Gonsalves), seeds from the most promising *p25*-transgenic lines were sent to Hawaii in 2004 for a field trial to test the potential resistance of these plants to natural challenge in an area where severe CTV strains and the efficient vector *Toxoptera citricida* are predominant.

The *p25* gene of CTV has also been inserted into sour orange, and transgenic plants accumulating or not the *p25* protein have been generated (Ghorbel *et al.*, 2000). However, resistance of these plants to tristeza decline was not evaluated because this syndrome is not usually reproduced under greenhouse conditions and a permit to transfer these plants to the open field could not be obtained yet. The inverted-graft test (Pina *et al.*, 2005) was used as alternative. It consists on grafting the scion genotype onto CTV-infected sweet orange rootstocks in the greenhouse. Those genotypes that are resistant to tristeza decline are able to sprout and develop normally, while susceptible genotypes show serious difficulties in sprouting and usually abscise a few weeks after grafting. Unfortunately, none of the *p25*-sour orange transgenic lines resulted resistant to tristeza decline in this assay.

In an attempt to develop RNA-mediated resistance against CTV, Mexican lime plants were transformed with two untranslatable versions of the *p25* gene from CTV isolate T305: (1) the full-length *p25* gene modified by introducing two consecutive stop codons three nucleotides downstream the start codon, and (2) the 3' half of *p25* gene fused to the *sgfp* marker gene, both under the control of the 35S promoter. Of the 48 transgenic lines obtained, 35 harbored the untranslatable full-length *p25* gene and 13 carried the truncated version, as revealed by Southern blot hybridization. Furthermore, run-on assays and cytosine methylation analysis showed that the *p25* transgene was post-transcriptionally silenced in some of the lines (Domínguez *et al.*, 2002a). After graft-inoculation with CTV T305, all transgenic plants developed symptoms, though some delay in virus infection and symptom attenuation was observed in the first two flushes postinoculation, especially in lines transformed with the full-length nontranslatable construct. However, in the third and following flushes, all transgenic plants accumulated CTV as the nontransgenic controls (Domínguez *et al.*, 2002b).

Yang *et al.* (2000) reported production of Rio Red grapefruit transgenic plants containing an untranslatable version of the *p25* coat protein gene from CTV and the *Galanthus nivalis* agglutinin gene, a plant-derived insecticidal gene.

Febres *et al.* (2003) transformed Duncan grapefruit with several CTV-derived sequences, including *p25* from three different strains and a nontranslatable version of the same gene, *p27*, the replicase gene, and a 400 bp segment of the 3' end of the genomic RNA in either sense or antisense orientation (*see Grapefruit* for description of these works).

Olivares-Fuster *et al.* (2003) used two constructs derived from the 3'-UTR of CTV T36, under the control of the 35S promoter, to transform Itaborai sweet orange protoplasts. They were used in sense orientation and were able to transcribe the 393 and 742 3'-terminal nucleotides of the viral genome. Protoplast lines were challenged with CTV, and 4–5 days later viral replication was tested by Northern blot. Two of the clones showed reduced replication and one clone carrying the larger construct showed null replication. Unfortunately, attempts to regenerate whole plants from these clones were unsuccessful. Leandro

Peña's group has used a construct derived from the 3'-terminal 550 nucleotides from CTV T36 to transform Mexican lime. It was engineered to express this fragment either in sense or in antisense orientation, under the control of the 35S promoter. More than 20 independent transgenic lines were generated with each construct. After propagation and challenge by graft-inoculation, none of them was immune to infection, though several plants showed delayed infection (Fagoaga *et al.*, unpublished results).

The 3'-terminal gene of CTV codes for a 23-kDa protein (p23), which is an RNA-binding protein that contains a motif rich in cysteine and histidine residues in the core of a putative zinc-finger domain (López *et al.*, 2000). This protein is involved in regulating the balance of plus and minus RNA strands during replication, with the zinc finger domain and the adjacent basic region being indispensable for asymmetrical accumulation of the plus strand (Satyanarayana *et al.*, 2002). Considering its regulatory role in CTV replication, we decided to explore whether overexpression in transgenic plants of this protein could affect the normal CTV infectious process, we have produced more than 50 transgenic lime plants carrying the *p23* gene from CTV T36, or a truncated version thereof, both types under the control of the 35S promoter. Constitutive expression of *p23* induced phenotypic aberrations resembling symptoms incited by CTV in nontransgenic lime plants, whereas transgenic plants expressing the *p23*-truncated version were normal. The onset of CTV-like symptoms in *p23*-transgenic plants was associated with the expression of p23, and its accumulation level paralleled symptom intensity (Ghorbel *et al.*, 2001a).

To determine whether expressing ectopically the *p23* gene from a severe and a mild CTV strain induced similar phenotypic effects on Mexican lime, a second set of transgenic limes was produced using the *p23* gene from either the severe strain T36 or the mild strain T317. Ectopic expression of the *p23* gene induced in Mexican lime aberrations resembling viral leaf symptoms of similar intensity, irrespective of the pathogenicity of the CTV strain from which *p23* was obtained, and this was correlated again with accumulation of p23 protein. Transformation with *p23*-T36 of other CTV susceptible citrus species, including sweet and sour orange, and of the CTV-resistant *P. trifoliata*,

also led to CTV-like symptoms that were not visible when these plants were transformed with a truncated *p23* version. The intensity of CTV-like symptoms in citrus species and relatives other than Mexican lime correlated with levels of *p23* transcripts, but the p23 protein was barely detectable in these hosts. The higher accumulation of p23 in Mexican lime with respect to sweet and sour orange was also observed in nontransgenic plants inoculated with CTV, suggesting that even minimal levels of p23 cause deleterious effects in the latter two species. In contrast, transgenic expression of *p23* in CTV nonhost *Nicotiana tabacum* and *Nicotiana benthamiana* species led to consistent accumulation of p23 without phenotypic aberrations. Altogether, these results indicate that p23 is an important CTV pathogenicity determinant that interferes with plant development specifically in citrus species and relatives (Fagoaga *et al.*, 2005). In addition, p23 has been found to act as an RNA silencing suppressor in *N. tabacum* and *N. benthamiana* plants (Lu *et al.*, 2004).

In course of the experiments to incorporate *p23* into Mexican lime, 3 out of 60 lines carrying the *p23* gene of CTV T36 and 2 out of 20 lines carrying that of CTV T317, were visually normal and developed as controls transformed with the empty vector or nontransformed (Figure 10). These five lines displayed characteristics typical of PTGS: multiple copies of the transgene and methylation of the silenced transgene as revealed in Southern blot analyses, low levels of the corresponding mRNA in Northern blots, and accumulation of *p23*-specific siRNAs as shown in ribonuclease protection assays. When propagations of these silenced lines were graft- or aphid-inoculated with CTV T308 and T300, respectively, some were immune: they neither expressed symptoms nor accumulated virions and viral RNA as estimated by DAS-ELISA and Northern blot hybridization, respectively. Other propagations were moderately resistant because they showed delayed expression of leaf symptom and attenuated stem pitting compared to the controls. The susceptible propagations, in addition to normal symptom expression and elevated virus titer, accumulated *p23*-specific siRNAs at levels significantly higher than immune or noninoculated propagations, and showed transgene demethylation (Fagoaga *et al.*, 2006).

Figure 10 Engineering resistance to citrus tristeza virus (CTV). Nontransgenic control (left) and *p23*-silenced transgenic (right) Mexican lime plants graft inoculated with CTV. Transgenic plant shows resistance to viral infection while control plant shows CTV symptoms such as vein clearing and leaf cupping

A characteristic of the *p23* transgene-mediated PTGS was that vegetative propagations from the same transgenic line showed different responses against CTV, with some propagations being immune and others susceptible to viral challenge. This variable response among clonal transformants carrying viral-derived transgenes indicates that factors other than the genetic background of the transgenic plant, such as environmental conditions or the developmental stage, play a key role in PTGS-mediated resistance. As mentioned above, Fagoaga *et al.* (2006) also observed a high accumulation of viral-specific siRNAs in CTV-inoculated nontransgenic (or transformed with the empty vector) Mexican lime plants, indicating a strong natural PTGS-mediated antiviral response in this host. These results indicate that most of the siRNAs detected in susceptible *p23*-transgenic plants come from degradation of viral RNAs, and that the resistance obtained in immune plants was likely triggered by the small amounts of the transgene-specific siRNAs existing before CTV inoculation. A connection can also be inferred between the high accumulation level of siRNAs in CTV-infected plants and cross-protection induced by mild CTV strains: in line with the accepted PGTS model (Hammond *et al.*, 2000), the siRNAs derived from mild cross-protecting CTV strains could prevent or attenuate the subsequent invasion by a severe CTV strain through their incorporation into an RNA-induced silencing complex targeting for degradation the genomic and subgenomic viral RNAs.

More recently, Batuman *et al.* (2006) have engineered a construct consisting of the *p23* gene

plus 3'-UTR from CTV in sense and antisense, separated by the Castor bean catalase intron, under the control of the 35S promoter, which once expressed in transgenic cells should be folded into a double stranded (ds) RNA structure theoretically able to trigger PTGS. It was used to transform *N. benthamiana* and *C. macrophylla*. Integration and expression of the transgene was demonstrated by Southern and Northern blot, respectively. Seventy *C. macrophylla* transgenic plants coming from 35 independent lines were challenged with CTV by graft-inoculation, but only 9 lines showed a delay in viral infection. None showed durable protection against CTV. Nevertheless, transgenic lines accumulated transgene-derived mRNA usually at high level, and neither siRNA accumulation nor transgene methylation was characterized. We have used a similar construct to transform Mexican lime plants, selected those lines carrying a single copy transgene and accumulating siRNAs at high levels, and challenged 6–11 propagations from them with CTV by graft-inoculation. A variable number of propagations from some of these lines were fully resistant to CTV challenge (Cervera *et al.*, unpublished results).

In summary, these studies demonstrate that PDR can be extended to a member of the family Closteroviridae and to its natural hosts. Whether transgenic citrus plants expressing CTV-derived sequences could be an efficient alternative to cross protection for controlling stem pitting CTV strains in the field, and whether resistance to tristeza decline could be incorporated to the sour orange rootstock, remains to be tested.

An alternative strategy to look for resistance against CTV could be using plant-derived resistance genes. General resistance to CTV has been found in *P. trifoliata*, and a resistance gene (*Ctv*) has been characterized and mapped (Gmitter *et al.*, 1996; Mestre *et al.*, 1997; Fang *et al.*, 1998). Because of the complex genetics of citrus, it is extremely difficult to introgress this resistance gene into citrus varieties by conventional breeding. However, cloning of this gene is underway in several laboratories (Deng *et al.*, 2001; Yang *et al.*, 2003). A bacterial artificial chromosome (BAC) library developed from *P. trifoliata*, homozygous to *Ctv*, was used for a 1.2 Mb genome walk spanning the region between *Ctv*-flanking markers. Sequencing of a set of four overlapping BAC clones in this region, using shotgun sequencing and resolution of their ends by sequencing of additional BAC clones and their use as anchors, further localized *Ctv* to a 282 kb region, comprising 22 predicted genes (Yang *et al.*, 2003). Sequence analysis of the *Ctv* locus in this region identified 61 SSRs, which were used to further narrow down the locus in the *Poncirus* genome to 121 kb, comprising 10 genes. Each of the 10 genes in this region has been individually cloned in *Agrobacterium*-based binary vector and used to transform susceptible Ruby Red, Rio Red, and Duncan grapefruit varieties in Eric Mirkov's laboratory (Rai, 2006). Although results from the CTV challenge experiments are still preliminary, transgenic lines carrying and expressing either of the 10 candidate genes were susceptible to CTV infection, suggesting that more than one gene in the locus is involved in resistance to CTV or that the role of other genomic loci has been overlooked (*see also Grapefruit*).

Citrus mosaic virus (CiMV) is a serious constraint for citrus production in Japan. Infected trees grow poorly and often develop ringspot symptoms on the fruit, which drastically reduce their commercial value. Iwanami *et al.* (2004) reported the incorporation of the coat protein gene from CiMV into *P. trifoliata*, the main citrus rootstock in Japan. More than 30 transgenic lines were produced and characterized by Southern blot. Attempts to detect coat protein immunoreaction in the transgenic plants by Western blot failed. More than 20 transgenic lines were propagated and mechanically inoculated with the virus. One line showed resistance to virus challenge (7.1%

infection, compared to 65.1% infection in controls at 60 days postinoculation) while the other lines showed responses ranging from susceptibility to more moderate resistance at the same time period. There are plans to transfer the most promising lines to the field and challenge them against the virus under natural conditions.

Citrus canker, caused by the bacterium *X. axonopodis* pv. *citri*, is one of the most important diseases in several citrus areas, and there are no ways to control it other than accomplishing very expensive eradication programs in regions where limited number of foci are periodically identified, or applying massive doses of chemicals that only make a partial control and cause adverse effects in the environment. Attacins belong to a class of antimicrobial peptides, which are secreted by several insect species into the haemolymph in response to bacterial infections. Transgenes encoding attacin precursors have been used to reduce susceptibility to *Erwinia* species in transgenic pear, apple, and potato plants, but the mechanism of resistance is still unknown. Boscardi *et al.* (2006) introduced the attacin A gene (*attA*) from *Tricloplusia ni* under the control of a double 35S promoter into Hamlin sweet orange seedlings. Interestingly, the transgene-derived protein carried a native signal peptide that secreted it to the apoplast, as it was demonstrated by transiently expressing *attA-gfp* and *attA-uidA* fusion constructs in onion cells. Propagated plants from eight Southern and Northern blot-positive lines were spray-inoculated with a 10⁶ CFU/ml canker bacterial suspension and incubated in a growth room set at 27°C during 1 month, when disease severity was assessed by calculating diseased leaf area in 15 young leaves per transgenic line. Seven lines showed a significant reduction in susceptibility to citrus canker, and in two of them the reduction was of 55% and 60% compared to the control.

Citrus blight is a devastating disease of unknown etiology, which causes general decline of trees in hot and humid areas. A pathogenesis-related (PR) protein of about 12 kDa can be detected in trees affected by blight, and it is not found in citrus trees with other disorders and diseases. The *p12* gene was isolated from a cDNA library from roots of a tree with citrus blight and used in sense or antisense, under the control of the 35S promoter, to transform Carrizo citrange plants.

Stable integration was confirmed by Southern blot, and expression was verified by Northern blot and by Western blot (in sense plants). Accumulation of the p12 protein in sense plants did not provoke any symptom or developmental abnormality, suggesting that this protein is not involved in symptom expression. The precise role of p12 in citrus blight requires further investigation (Kayim *et al.*, 2004).

2.6 Stability of Transgene Expression and Phenotype; and Effects on Growth, Yield, and Quality

A major requisite for evaluating the validity of genetic transformation technology in improvement programs is the stability of the modified genome and the stability of transgene integration and expression over long periods of time, especially in vegetatively propagated and long-lived perennial fruit crops. However, reports on transgenic stability in citrus are almost nonexistent, and most works are focused in introducing a transgene of potential agricultural interest into a given genotype and evaluating the phenotype of the regenerating plants only after few months of growth in the greenhouse and normally just pertaining the trait, which is tentatively modified.

However, somaclonal variation induced during the *in vitro* culture phase has been extensively reported in greenhouse experiments and field trials of transgenic plants. It has been used in citrus as a strategy to generate genetic variation that could be potentially useful in improvement programs (Grosser *et al.*, 2002), but somaclonal variation could also affect plant phenotypes producing abnormal morphologies, which has been correlated with genomic changes as chromosomal deletions and alterations in ploidy. In addition, expression of transgenes can be affected by numerous causes, as transgene loci number, genomic context of the integrated loci or position effects, abnormal configurations of the integrated T-DNA, or even environmental conditions that may contribute to differences in expression between plants with unlikely integration patterns.

Cervera *et al.* (2000b) maintained a collection of 70 transgenic citrange plants grown in 50l-pots in a screenhouse in order to investigate, for a period of 4–5 years, (1) the origin of

morphological variants in the transgenic population, (2) how factors related to T-DNA integration, regeneration process and expression of transgenes may be influenced by transformation conditions, (3) whether transgenes are stably integrated and expressed over long time periods in citrus plants grown under natural environmental conditions, and (4) whether correlation between integration patterns and transgene expression could be established in these plants (Cervera *et al.*, 2000b).

Transgenic plants used for this analysis were generated earlier (Peña *et al.*, 1995b; Cervera *et al.*, 1998c). Briefly, *A. tumefaciens* EHA 105 containing the binary plasmid p35SGUSINT was used as vector for transformation of epicotyl segments from *in vitro*-grown seedlings. Two co-cultivation media were used: in the first case it contained BAP at 1 mg l^{-1} as growth regulator (type 1), and in the second, co-cultivation was performed in the medium rich in auxins (2 mg l^{-1} 2,4-D, 2 mg l^{-1} IAA, and 1 mg l^{-1} 2-iP as phytohormones) (type 2). All the transgenic plants were confirmed as *nptII*- and *uidA*-positive by Southern blot analysis. First of all, isozyme analysis allowed to confirm that the same banding pattern was found for all the samples, which corresponded exactly to the pattern shown by the female parent from which the starting seeds were taken. These results indicated that no zygotic plants had been recovered from our transformation experiments and that all the plants were nucellar, maintaining the Carrizo citrange maternal genotype, with the exception of differences in transgenes integration loci.

Four phenotypic variants were detected among the transgenic population. Several morphological features made these plants distinguishable from the maternal phenotype: they developed thicker and broader leaves, with darker green color, and usually with broader petiole wings, and showed a slower growth. Ploidy tests of the whole plant collection demonstrated that all the plants in the population were diploid except these four plants, which were tetraploid. Transgenic tetraploids could have been originated either by a process of polyploidization during *in vitro* culture or more likely by the regeneration of transgenic shoots from tetraploid plant tissue, since more than 10% of the Carrizo citrange seedlings germinated *in vitro* are tetraploid.

Somaclonal variation may be common after exposition of explants to auxins, which is used as stimulus for cell de-differentiation, division, and consequently callus induction. This de-differentiated state makes cells more likely to integrate foreign DNA (Peña *et al.*, 2004b) but at the same time more predisposed to genomic alterations. Nevertheless, we did not find phenotypical differences between plants of type 1, obtained after transformation on a culture medium without auxins, and plants of type 2 that were obtained after transformation on a culture medium rich in auxins and thus after regeneration through a prominent callus phase.

The follow up of the population of transgenic plants by means of histological and fluorimetric GUS analyses confirmed the stable expression of the *uidA* transgene in all the plants over a period of 4–5 years. Patterns of expression were comparable for each line in successive histochemical analyses, although differences of 40% on measured values could be detected in fluorimetric assays, making the quantification of transgene activity over years very difficult. These fluctuations in time could be attributed to the developmental and physiological state of the plants. Almost one third of the population exhibited a typical pale blue staining pattern, recurrent in histochemical analyses performed during several years that correlated with very low values of expression measured by fluorescence analyses. These plants seemed to be undergoing a process of transgene silencing. A correlation between the pale blue color in leaf pieces and PTGS phenomena in citrus was corroborated in subsequent experiments (Dominguez *et al.*, 2002a, 2004). Any transgenic plant with complete silencing was not detected among the population, which may be reasonable since the recovery of transgenic plants was performed after a histochemical GUS assay of regenerating shoots, and only those showing a detectable GUS blue staining were shoot-tip grafted and allowed to progress into whole plants. This selection scheme was possibly delimiting the recovery of plants in which total silencing phenomena could be occurring.

The most frequent number of T-DNA inserts was one and two, but plants having possibly more than six *uidA* copies were also found. According to the data from Southern blot analyses, it is suggested that at least 35% of the analyzed plants

had integrated multiple T-DNA rearranged inserts at one locus. A significant tendency to low *uidA* expression levels was confirmed for transgenic citrus plants with more than two T-DNA copies, but levels of expression were highly variable for plants having only single copy. Our data agree in general with the results described by other authors, since although it has been frequently reported that single copies of a transgene are generally more stably expressed than multiple or rearranged insertions, a clear-cut correlation has not been found. Copy number, position effects, and organization of a given insert could account as a whole for the highly variable levels of expression displayed by the transgenic plants.

To investigate more deeply the actual incidence of transgene silencing in citrus, we decided to use a population of transgenic Mexican lime plants regenerated under *uidA/nptII* selection (type A), and a second one regenerated without marker selection but confirmed as transgenic by PCR (type B) (Dominguez *et al.*, 2002a). Irrespective of the recovery scheme used, most of the transformants (at least 59%) showed T-DNAs arranged as tandem repeats. The high frequency at which these complex structures were found, and their configuration as direct repeats (DRs) or inverted repeats (IRs), either on the right border (RB) or on the left border (LB), supports the hypothesis that the T-DNA is made double stranded prior to integration and that repeats are formed by extrachromosomal homologous recombination.

Regeneration of transgenic limes under nonselective conditions resulted in the production of plants with silenced transgenes at high frequency. Furthermore, silencing affected all the transgenes of the T-DNA in all silenced lines. When organization of T-DNA was analyzed in silenced and nonsilenced lines, it was observed that IRs were exclusive of silenced transformants, establishing a clear-cut correlation between both the phenomena. About 30% of the lines regenerated under nonselective conditions were silenced, whereas none of the lines recovered after *nptII* and *uidA* selection showed transgene silencing. These results indicated that under selective conditions only transgenic events expressing the marker genes could be detected, thus precluding the possibility of recovering transgenic plants with silenced transgenes along the whole T-DNAs. Moreover,

more than 5% of the regenerants obtained without marker selection were actually transgenic plants, opening the way for the production of citrus transformants without marker genes by PCR screening.

Gene silencing in citrus was further investigated by Domínguez *et al.* (2004). In this report, all Mexican lime regenerants obtained after kanamycin selection that resulted either GUS-positive or GUS-negative were analyzed by Southern blot. Interestingly, one-fourth of the GUS-negative plants were not escapes but transgenic plants showing *uidA* silencing, indicating that the transformation efficiency was underestimated when it was based in reporter marker gene expression.

Although genetic instability is usually a non-desirable trait in transgenic plants, Trainin *et al.* (2005) proposed the use of genetic transformation as a tool to induce mutagenesis in citrus by transposon tagging that could be used to identify mutants in genes of interest. Unless silenced, an intact transposon introduced into a plant will keep transposing and generating mutations for years converting transformed trees into mutation machines. With this purpose, Trainin *et al.* (2005) transformed Duncan grapefruit plants with a construct consisting of the *uidA* gene controlled by the 35S promoter but with the *Ac* transposable element cloned between the promoter and the marker gene, so GUS activity would result only if *Ac* excision occurred. However, this system had major drawbacks because transposition could not be controlled that caused in most cases tiny sectors if the transgenic plants, making detection of any mutant phenotype very difficult.

To investigate the effects of transgene incorporation and expression on tree growth and development, and fruit yield and quality, it is necessary to perform field trials. Unfortunately, there are only two field trials with citrus trees so far in which genetically modified plants are growing in the field over years under diverse environmental conditions. A release of transgenic citrus plants under controlled field conditions is being performed at the IVIA (Valencia, Spain) since 1997. The release site is located in an experimental field with an area of 1638 m². There are 130 trees, including 16 transgenic plants of Pineapple sweet orange, 16 transgenic plants of Mexican lime, and 16 transgenic plants of Carrizo citrange.

There are two plants from eight independent transgenic lines for each case. In all cases, the transgenes integrated were 35Spro::*uidA*::NOSter and NOSpro::*np1II*::NOSter, providing GUS expression and resistance to kanamycin, respectively. In addition, there are 8 nontransgenic control plants from each of the species and an external border of 58 nontransgenic trees of *Clemenules clementine* (Figure 11).

The purpose of the release is to investigate (1) morphological and phenological characteristics of the transgenic trees, (2) expression of the transgenes in different tissues and organs, (3) stability of the transgenes, (4) transmission of the transgenes to the progeny, and (5) possibility of transgene dispersal through the pollen to nontransgenic monoembryonic citrus trees (*Clemenules clementine*). The trial was approved by the Spanish Ministry of Environment (permit Nr. B/ES/96/15) and was in accordance with Article 9 of Directive 90/220/EEC of the European Union. This was the first release in the world of transgenic citrus plants to the field. Until now, transgenic plants are morphologically and phenologically normal, as nontransgenic controls, and transgenes are stably expressed over different seasons and in different plant tissues and organs. Tree phenology and fruit quality have been evaluated during three consecutive years for each tree. Phenological calendar was made by observation and description of phenological stages of development every 2 weeks. Fruit analysis is being made once a year when fruit is ripe and full colored. The parameters analyzed to determine fruit quality are weight, volume, caliber, color, acidity, Brix, juice weight, juice volume, % solid weight (juice weight/fruit weight) and maturity index (Pons and Peña, unpublished results).

A second field trial is being performed in Weslaco (Texas, USA) with Rio Red grapefruit transgenic plants (*see Grapefruit*). In addition, seeds from Mexican lime transgenic plants carrying a CTV-derived transgene encoding the major coat protein gene *p25* were sent to Hawaii in 2004 to carry out a field trial to test the potential resistance of these plants to CTV under natural challenge conditions, as part of a collaboration project of the IVIA with the University of Hawaii (M. Melzer, S. Ferreira, and J. Hu) and the USDA (D. Gonsalves).

Figure 11 Release of genetically modified citrus plants under controlled field conditions at the IVIA. (a) Schematic diagram of the trial. There are 130 trees, including 16 transgenic plants of Pineapple sweet orange (Pi), 16 transgenic plants of Mexican lime (MI), and 16 transgenic plants of Carrizo citrange (Cc) (2 plants from 8 independent transgenic lines numbered from 1 to 8; gray circles). In addition, there are 8 nontransgenic control plants from each genotype (black circles). There is also an external border of 58 nontransgenic trees of *Clemenules clementine* (CN; white circles). (b) Photograph taken 10 years after the field trial was established. It shows the Pineapple sweet orange row (left), the Carrizo citrange row (centre), and the Mexican lime row (right). Most proximal and surrounding trees correspond to the *Clemenules clementine* border

2.7 Specific Regulatory Measures Adopted

The European Union currently regulates the activities performed with genetically modified organisms (GMOs) through two basic Directives: Directive 98/81/CE, on the confined utilization of GM microorganisms, including transgenic plants, and Directive 2001/18/CE (repealing the above-mentioned Directive 90/220/EEC) on the deliberate release into the environment of GMOs. Several other regulations have been adopted later,

as those related to GMOs in human food and animal feed, other on the labeling and traceability of GMOs, or other on cross-border movement of GMOs.

Both these European Directives were incorporated to the Spanish legislation through the Law 9/2003 on the confined use, deliberate release, and commercialization of GMOs. Regulation 178/2004 approved and established the general framework for the development and execution of the Law 9/2003. In Spain, competencies on

confined utilization and deliberate release rely on Regional Governments, and commercialization entirely depends on the National Government. At the practical level, confined utilization of transgenic citrus plants, either in laboratories, phytotrons, or special greenhouses (those in which transgenic pollen release is prevented), is usually considered at the type 1 level (lowest risk in the scale of 1–4) by the competent authorities. If this is the case, it only requires a notification of the activities that are being carried out but does not need any specific authorization by the competent regulators. Regarding deliberate release of transgenic plants, much more detailed information is requested in any submitted notification, including data on the genetically modified plant (identity of the recipient, description of modified traits, type of genetic modification, etc.), information relating to the experimental release (purpose of the release, geographical location, size, etc.), potential environmental impact of the release, description of any measures taken by the notifier for the control of risks including isolation designed to limit dispersal, and planned field trials designed to gain new data on the environment and human health impact of the release (where appropriate). Notifications are publicly available. In Spain, there is a Biosafety National Committee, which is a technical board mostly composed of well-recognized independent experts that recommends to the competent National and Regional Authorities on approval or rejection.

It is important to point out that the Article 4 of the Directive 2001/18/CE says that “Member States and the Commission shall ensure that GMOs, which contain genes expressing resistance to antibiotics in use for medical or veterinary treatment are taken into particular consideration when carrying out an environmental risk assessment, with a view to identifying and phasing out antibiotic resistance markers in GMOs, which may have adverse effects on human health and the environment. This phasing out shall take place by the December 31, 2004 in the case of GMOs placed on the market and by December 31, 2008 in the case of GMOs authorized for deliberate release.”

In Valencia region, the legislation on confined utilization and deliberate release of GMOs was approved in 2006, meaning that during the precedent 8 years Leandro Peña’s group could

not submit any notification on these issues because there was no competent authority in our region. From now on, we are preparing five new notifications for deliberate release of transgenic citrus trees, which have been modified in disease resistance, tree performance, and fruit quality aspects.

3. FUTURE ROAD MAP

3.1 Expected Products

There are citrus areas seriously threatened by diseases caused by bacteria. It is the case of Huanglongbing, induced by the bacterium *Candidatus* L. asiaticum, which has impeded the development of citrus industries in Southeast Asian countries. It is also a limiting factor for increasing citrus productivity in China. The bacterium affects all citrus types making trees unproductive, and there are no means of efficient control other than almost permanent insecticidal treatments to fight against the psyllid vector. *Candidatus* L. asiaticum and the apparent variant *Candidatus* Liberibacter americanus were first detected in Sao Paulo state (Brazil) in 2004 and an eradication program was started 1 year later. In about 1 year, more than half million affected trees have been removed. *Candidatus* L. asiaticum was also found in Florida (USA) in 2005 and the disease is spreading from south to north without control. In this area, the situation is even worse due to the impossibility to eradicate citrus canker, caused by the bacterium *X. axonopodis* pv. *citri*, and affecting all economically important varieties cultivated in the region. Therefore, looking for resistance mainly against *Liberobacter* spp. but also against *X. axonopodis* pv. *citri* is a major priority for the most important citrus industries in the world. Probably, the only opportunity for getting durable resistance against these diseases could come from the incorporation of transgenes able to efficiently protect the most relevant variety and rootstock genotypes grown in these areas from the bacteria and/or their vectors.

There are other pests and diseases caused by other bacteria, viruses, fungi, nematodes, etc. that are not so serious but limit production and fruit quality in certain citrus areas depending on the pathogen. Among them, much effort has been

invested in attempting to incorporate transgenic resistance to CTV into citrus genotypes used as rootstocks and varieties. It can be predicted that this will continue as an important objective, and that strategies based on either PDR or plant-derived resistance will be further investigated.

Since markets of developed countries demand fresh fruit of increasing quality and with less agrochemical treatments, and also better and richer juice, more research will focus in understanding genetic control of metabolic pathways regulating carotenoid, flavonoid, limonoid, and monoterpene/essential oil biosynthesis with the aim of modifying fruit color and aroma, increasing vitamin content and reducing bitterness. In the same way, a better knowledge of citrus maturation and of determinants of sugar and acid content is important to attempt modulation of these traits in transgenic fruits. Seedlessness is another trait that has been successfully achieved in annual crops, and similar strategies could be used to afford this in citrus. Most strategies related to transgenic improvement in citrus fruits would require the use of tissue-specific promoters.

Considering that citrus trees are composed of scion and rootstock genotypes and the lack of current acceptance of transgenic foods by the consumer, it is logical to think that genetic modification of rootstock traits will be emphasized in the near future. In this sense, increasing tolerance to abiotic stresses (salinity, drought, etc.), to rootstock diseases (CTV, *Phytophthora* spp., nematodes, etc.), and adapting tree architecture to managing schemes requiring less labor and land, could become research areas of major interest.

In spite of the increasing number of laboratories working on development of genetic transformation systems for citrus and on the search for potentially useful transgenes derived from widely diverse source organisms, the lack of basic knowledge on citrus and citrus pathogens biology and the difficulties of working with genetically complex tree species, make very difficult to produce new improved transgenic genotypes of real agricultural importance.

3.2 Addressing Risks and Concerns

To our knowledge, the only transgenic citrus field trial in which environmental risk is being assessed

is that performed at the IVIA, and researchers are exclusively investigating the frequency of transgenic pollen dispersal. Since 2001, the number of transgenic seeds expressing the *uidA* gene has been yearly assessed in fruits produced by the nontransformed monoembryonic Clemenules clementine border trees surrounding the transgenic trees. Clementines are self-incompatible and parthenocarpic, meaning that they can produce fruits without seeds. Seeded fruit results only in case of cross-pollination. As border trees are very close to the transgenic trees (3–6 m), these are the most probable pollinators of clementine flowers. Even under this situation, the frequency of GUS-positive seeds is being less than 1% year by year (Pons and Peña, unpublished results).

In addition, there are characteristics of citrus biology and cultivation that should be strongly considered when environmental risks are assessed in transgenic field trials, and that depends on the citrus area of the world and the transgenic genotypes that are going to be evaluated. Commercial citrus varieties are propagated vegetatively by grafting of well-known genotypes onto well-known rootstocks. In our Mediterranean conditions and considering the citrus genotypes used, it is not possible that transgenic plants could become weeds. There are no wild citrus species and relatives in Europe, so there are no possibilities of compatible interactions between transgenic and wild plants. The situation would be completely different in Southeast Asia regarding this issue.

Citrus cultivars grown in some citrus areas are sexually compatible with many transgenic citrus genotypes that would be desirably produced. Under natural conditions, cross-pollination between transgenic lines and cultivated genotypes would be theoretically possible in many cases. Pollination in citrus is exclusively performed by insects, bees being the most successful pollinators. In areas where citrus is commercialized as fresh fruit, most varieties are sterile or self-incompatible, but the former are usually cross-compatible, leading to seed development. As presence of seeds in the fruit drastically reduces its price, affecting possible commercialization, cross-pollination in citrus is usually prevented by farmers by using different cultural practices and treatments. Most citrus species are parthenocarpic. In contrast, in areas in which fruit industry is based on juice production,

cross-pollination and presence of seeds is not a matter of concern. In any case, if cross-pollination occurs, transgenes will only be expressed in the seed, which is never consumed and is not used for propagation of varieties. In the incidental case that transgenic seedlings could germinate in an orchard, they could be removed by farmers as it is usually done with any citrus seedling germinating in any orchard in most citrus areas. Moreover, these seedlings would never flower before being removed because citrus seedlings are juvenile and thus, they need several years to start flowering.

With the aim to assess the potential risk of horizontal gene transfer between GM-citrus plant material and food-associated bacteria, Weiss *et al.* (2007) investigated the effect of conditions required for orange juice processing on the stability of DNA from transgenic Pineapple sweet orange. Results showed that genomic DNA from orange juice suffered degradation within 2 days of storage, indicating that current standard industrial procedures to pasteurize orange juice as well as its acidic nature caused a strong degradation of genomic DNA below sizes reported to be suitable for horizontal gene transfer.

3.3 Expected Technologies

The primary function of genetic transformation in citrus is the development of new improved varieties and rootstocks based on otherwise genotypes of excellent quality but deficient in one or a few characteristics. However, genetic transformation has been usually attempted and applied to a restricted list of economically important genotypes. In this sense, there are a few or no reports on transgenic satsuma and clementine mandarins, navel and Pera sweet oranges, Eureka and Lisbon lemons, Rangpur lime or sour orange. More importantly, most of the work on citrus transformation has been performed with juvenile material, which will need many years to start flowering and fruiting and several years more to fully lose the juvenile characteristics. To gain a real profit from genetic transformation as a tool for citrus improvement, development of efficient transformation systems for mature tissues becomes an obligate task. Currently, Leandro Peña's group works almost

exclusively in mature citrus transformation, but few laboratories are using this approach. It could be claimed that juvenile material is highly responsive and that it could be used at least to investigate gene function, but as the main target of citrus genetic improvement for the industry of most citrus-growing areas is usually the fruit, transformation of mature plants is essential even for functional genomics studies. We developed a general basic procedure for genetic transformation of mature Pineapple sweet orange and are adopting it to many other citrus genotypes of interest. The mature transformation system highly relies on the use of plant material in excellent sanitary and ontological state, which is cultivated under extremely clean and very well controlled environmental conditions. Even with this, contamination of the plant material with saprophytes during the *in vitro* culture phase is still a limitation of the procedure. Other than this, transformation efficiency is still low for many genotypes of interest and more effort should be put in improving it.

Most transgenic improvement projects directed to fruit genetic modification depend on the use of tissue/organ-specific promoters. Moreover, appropriate transgene expression levels at specific developmental stages and under various environmental induction conditions could be ideal for certain improvement strategies aimed to increase disease resistance or higher abiotic stress tolerance. Rapid and reliable systems to evaluate regulatory sequences are required, especially for fruit tissues. Transient transformation procedures through either *A. tumefaciens* vectors or particle gun systems could be good alternatives to stable transgenic expression for testing promoter elements. Transient transformation could also be useful to test heterologous transit peptides that would direct the transgenically expressed protein to a given subcellular target site.

RNA interference-inducing hairpin vectors, in which target sequences are expressed simultaneously in sense and antisense (Watson *et al.*, 2005) are excellent tools to knock down putative genes of unknown function and thus decipher their possible role in citrus growth and/or development. They could be used for both genetic improvement projects and delineation of basic gene functions. At the same time, new transformation vectors are being designed, as those minimizing transgene

expression fluctuations through the use of transgene flanking matrix attachment regions (MARs) (Allen *et al.*, 2005), those precluding integration of plasmid vector sequences of prokaryotic origin that flank transgene expression cassettes (Kuraya *et al.*, 2004), or those allowing integration of large DNA inserts containing multiple genes, such as BIBAC (Binary-BAC) and TAC (transformation-competent artificial chromosome) vectors (Hamilton *et al.*, 1996; Liu *et al.*, 1999), to facilitate positional cloning and functional analysis of linked genes and for engineering complex metabolic pathways.

A European Union Directive forbids specifically the presence in transgenic plants of transgenes conferring resistance to antibiotics used for medical or veterinary purposes, due to concerns related to possible horizontal transfer of these genes to gastrointestinal bacteria. Although this is not affecting directly to *nptII*, it has been proposed its substitution by using only reporter marker genes or using herbicide resistance genes as alternatives for transgenic selection. In any case, the presence of marker genes in GMO foods prevents their public acceptance. In plants propagated by seeds, it is possible to remove the marker gene once transgenic plants have been recovered, by means of co-transformation with different transformation vectors and segregation of marker genes from the gene of interest in the transgenic sexual progeny. This is not feasible in vegetatively propagated plants and trees that possess very long juvenile periods.

An alternative comes from the use of the *manA* gene that encodes PMI (Haldrup *et al.*, 1998). When mannose is added to the plant tissue culture medium, it is transformed to mannose-6-phosphate, which cannot be metabolized by plant cells. Transgenic cells expressing *manA* could be able to transform mannose-6-phosphate into fructose-6-phosphate, which would be used by plant cells as carbon source. Therefore, transgenic cells accumulating PMI could have a clear advantage (positive selection) over nontransformed cells, when explants are exposed to a tissue culture medium containing mannose and deprived of any other carbon source. This system has already been successfully used for juvenile sweet orange and Carrizo citrange transformation (Boscariol *et al.*, 2003; Ballester *et al.*, 2008).

Another attractive possibility is offered by the multiautotransformation (MAT) vector system that combines positive selection, using the *ipt* gene, with a site-specific recombination and DNA removal system that generates marker-free plants (Ebinuma *et al.*, 1997; Sugita *et al.*, 1999). The *ipt* gene is located in the Ti plasmid of *A. tumefaciens* and encodes the enzyme *ipt*, which catalyzes the production of a precursor of several cytokinins (Ebinuma *et al.*, 1997). Cytokinins are widely used to stimulate organogenesis in many cultured plant tissues, including citrus. The second interesting element of the MAT vector is the site-specific recombination system *R/RS* from *Zygosaccharomyces rouxii* (Sugita *et al.*, 1999), in which the recombinase *R* removes the DNA fragment placed between two recognition *RS* sites from the transgenic cells after transformation. In this vector, *RS* sites flank both the *ipt* marker and the *R* recombinase transgenes. After site-specific recombination and excision of the DNA fragment between *RS* sites, *ipt* marker-free transgenic plants may be obtained. Ballester *et al.* (2007) have successfully used this system in sweet orange and Carrizo citrange and are currently further exploring their possibilities to generate marker-free transgenic citrus plants that carry only the transgene of interest (Ballester *et al.*, 2008).

A third possibility is regeneration without selection and screening of all regenerants through PCR analysis. Using this system in Mexican lime, more than 5% of the regenerants resulted to be transgenic (Dominguez *et al.*, 2002a, 2004). We are further exploring this procedure with other citrus genotypes.

Transgene stacking could have an outstanding interest in citrus genetic improvement programs because it would allow incorporating a second transgene in an already improved transgenic line. More transgenes could be pyramided into the transgenic line showing the desired phenotype for the first and second transgenes and so on. The main advantage of this approach is that it is possible to check individual expression and phenotype conferred by each transgene before proceeding to the next transformation round. However, because of the long juvenility of citrus, the process can take extremely long time if more than 2 or 3 transgenes have to be introduced. Alternatively, we have used *API*-transgenic plants for

evaluating the possibilities of transgene stacking in citrus. *API* overexpression extremely shortens the juvenile period in citrus (Peña *et al.*, 2001). *API*-Carrizo citrange nucellar seedlings were successfully retransformed with a *gfp* vector and GFP-positive transgenic plants flowered and set fruits within 1 year after sowing, as *API*-Carrizo citrange controls (Cervera *et al.*, 2006; Cervera *et al.*, unpublished results). This could be then a valuable material and strategy to attempt functional genomics studies related to aspects of fruit and flower development by using reverse genetics. Furthermore, it can be used as a tool to rapidly evaluate putative fruit-specific promoter elements by stable transgenic expression. In addition, it could be an excellent tool for genetic improvement because transgene expression and phenotype evaluation related to modification of fruit characteristics could be readily achieved in less than a couple of years. However, for this purpose the *API* strategy should be combined with a gene removal system, as the R recombinase/RS target sequence mentioned above or other similar recombinase system, to eliminate the *API* transgene once it has fulfilled its early fruiting promotive function.

Recombinase systems represent a very interesting option for many different purposes in citrus transformation, because they could allow removal of marker genes and removal of transgenes of interest once their presence is not needed anymore in the plant (Dale and Ow, 1991). Moreover, they have been used to site-specific insertion of transgenes at specific loci by homologous recombination (Srivastava and Ow, 2002). However, this system and others proposing homologous recombination in the nuclear genome have still important limitations, related for instance to unexpected chromosomal rearrangements, unintended recombination, and generally very low efficiency (Gilbertson, 2003). Alternatively, chloroplast transformation through homologous recombination represents a feasible technology not only to get stable and uniform transgene expression, but also to achieve very high transgene product accumulation since it permits the introduction of thousands of copies of foreign genes per plant cell. Furthermore, transgene dispersal through pollen is avoided since the chloroplast is maternally inherited in most plants. The main obstacle of this approach is that

efficient chloroplast transformation is restricted to very few plant species (Daniell *et al.*, 2005).

3.4 Intellectual Property Rights (IPR), Public Perceptions, Industrial Perspectives, Political, and Economic Consequences

Genetic improvement through transformation requires active research in many fronts, including plant biology and physiology, phytopathology, biochemistry, molecular biology, genetics, and genomics, plus a good knowledge of the crop and its problems and the support of the industry to be able to develop new genotypes of real importance.

Multinational companies are able to cover all these aspects and concentrate in a few crops and improvement in a few traits to develop new products so important as for instance insect-resistant and glyphosate-tolerant corn, cotton, and soybean varieties. Their research lines are not only planned to decipher biological problems and publish their results in scientific journals but mainly to discover new patentable tools for genetic improvement of genotypes that will become also patentable or registrable and consequently will be part of their property. Many strategies for transgenic plant improvement are based on genes or sequences and regulatory sequences as well as on procedures for transformation or for marker elimination already patented by big companies. In contrast, most of the research on citrus transformation is being performed by small laboratories from academic or agricultural institutions, depending basically on Ph.D. students, with low-funded 3-year projects, without any patent policy, with very low support from the local citrus industry, and requiring very expensive facilities. In this context, it is easy to speculate that any future important development on citrus transgenic improvement will come from a company interested in this technology or from a committed public institution involved in citrus research and with big support from the industry, able to support the elevated costs of maintaining international patents and of mandatory biosafety tests required by the current legislation of most countries.

However, it is difficult for private companies to invest in transgenic improvement of citrus

now, because public perception in developed countries (especially in Europe and Japan) about GM-food is in general very negative and there are no signs of change of this situation in the coming future. It could be proposed to work on transgenic rootstock improvement, until scion improvement is accepted by the consumer. In any case, it remains to be seen whether fruit from a tree composed of a transgenic rootstock and a nontransformed variety is considered transgenic or not by the legislators and, more important, by the consumers. It is sad to see that more than 40 years after the first use of genetic engineering and 20 years after the generation of the first transgenic crop plants, the general public is unable to understand the benefits of the technology, and prefers to believe in catastrophic and unreasonable opinions from people with clearly defined political interests than in commitments and integrity of scientists working in public institutions. It is a matter of time that people will realize that genetic transformation is an excellent technology for crop improvement, in many senses much better and safer than other commonly used strategies. It is hard to predict nowadays whether public will need years or decades to accept these GM foods. In the meantime, genetic transformation is probably the most efficient approach to make reverse genetics in citrus to investigate gene function and thus to gain better understanding in metabolic processes and plant–pathogen–environment interactions. This will be essential for the future of citrus genetic improvement. In addition, the transgenic technology will be necessarily improved and most of the current concerns and risks on pollen dispersal, presence of marker genes, unintended transgene silencing, etc., will likely be overcome by new scientific and technological developments.

ACKNOWLEDGMENTS

The authors wish to thank J.A. Pina, C. Ortega, and A. Navarro for their excellent technical assistance. This research was supported by grants from the Ministerio de Educación y Ciencia (MEC-CICYT), Instituto Nacional de Investigaciones Agrarias, and Generalitat Valenciana, and is currently being granted by project AGL2006-03673/AGR.

1. INTRODUCTION

1.1 History, Origin, Distribution, and Uses

The genus *Citrus* includes some of the most important fruit varieties in tropical and subtropical regions, and grapefruit, *Citrus paradisi* Macf., is one of the most important commercial groups of citrus cultivars. The original grapefruit, first discovered in Barbados, is believed to be derived from a backcross of sweet orange, *Citrus sinensis* (L.) Osbeck, and pummelo, *Citrus grandis* (Gmitter, 1995; Nicolosi *et al.*, 2000). However, the most current commercial grapefruit cultivars have originated from nonconventional breeding methods such as bud sport selections or induced mutagenesis (Hodgson, 1967; Gmitter, 1995), with recent emphasis on pigmented cultivars. The United States is the world leader in grapefruit production, producing approximately 2 million tons annually (about 40% of the world total). Other countries with significant grapefruit production include South Africa, Israel, Mexico, and Cuba. Grapefruit production and consumption have been declining in the United States, but production is increasing in South Africa (Economic Research Service, USDA, 2005). Florida accounts for about 75% of the US grapefruit production, but significant quantities are also produced in

Texas, California, and Arizona. Most grapefruit is targeted for the fresh market, but there is also a significant processing industry that primarily utilizes fruit not making fresh market grade. Grapefruit essential oil also has value in the flavor and fragrance industries.

1.2 Threats to Grapefruit Production

Like other citrus species, grapefruit cultivars are genetically homogenous, which provides high yields of uniform high quality fruit, characteristics that are appreciated by both consumers and farmers alike. However, this same genetic uniformity makes grapefruit more susceptible to emerging pests and diseases, resulting in economically significant reductions in fruit quality and production. The main pathogens affecting grapefruit worldwide include *Citrus tristeza virus* (CTV) (Bar-Joseph *et al.*, 1989; Gmitter, 1995), psorosis (Rostacher, 1993), and citrus bacterial canker (*Xanthomonas axanopodis* pv. *citri*) (Xac) (Yang *et al.*, 2000; Vilorio *et al.*, 2004). Citrus canker has been declared endemic in Florida and threatens the existence of the world's largest grapefruit industry there. Another emerging disease posing a severe threat to citrus production (also now endemic in Florida) is citrus greening

disease or huanglongbing (HLB) caused by *Candidatus Liberibacter* spp. This bacterial disease is caused by a phloem-restricted pathogen that is vectored by the insect *Diaphorina citri* Kuwayama, a citrus psyllid (Texeira *et al.*, 2005). Along with developing resistance to these diseases, control of insect pests vectoring the pathogens is also contemplated in the general strategy for genetically improving citrus cultivars. Improvement of current grapefruit cultivars is a necessary demand not only for pest and disease resistance but also for fruit quality and availability as necessary to sustain and grow markets.

1.3 Grapefruit Variety Improvement

Grapefruit improvement via conventional breeding procedures has been hampered by large tree size, nucellar polyembryony, seedlessness, high levels of heterozygosity, long juvenility, and the relatively large land area and high costs necessary to grow and evaluate segregating populations (Grosser and Gmitter, 1990; Moore *et al.*, 2005). Popular red-fleshed low-seeded cultivars including “Star Ruby”, “Flame”, and “Rio Red” are the result of mutation breeding (irradiation) (Gmitter, 1995). Biotechnological methods other than classical breeding protocols being utilized to improve citrus species, including grapefruit and grapefruitlike hybrids, include interploid hybridization that can involve embryo rescue for triploid plant recovery and somatic hybridization for parent development (Grosser *et al.*, 2000; Grosser and Gmitter, 2005) and genetic transformation as featured in this chapter (Kobayashi and Uchimiya, 1989; Moore *et al.*, 1992, 2005).

Genetic transformation has become the most attractive alternative method for improving existing grapefruit cultivars (and other citrus), as it allows the introduction of one or two specific traits while maintaining cultivar integrity (Gmitter, 1994; Bond and Roose, 1998). The first reports of citrus transformation began to appear more than a decade ago, utilizing protoplasts (Kobayashi and Uchimiya, 1989; Vardi *et al.*, 1990; Hidaka and Omura, 1993), and *Agrobacterium*-mediated transformation of citrus cells (Hidaka *et al.*, 1990) and stem segments (Moore *et al.*, 1992), and finally particle bombardment of citrus cells (Kayim *et al.*,

1996; Yao *et al.*, 1996) with low transformation efficiency. After Moore *et al.* (1992) reported the successful use of nucellar seedling stem explants for *Agrobacterium* inoculation, attempts to optimize *Agrobacterium*-mediated transformation of stem and epicotyl segments in several citrus species resulted in continuously increasing transformation efficiency (Kaneyoshi *et al.*, 1994; Peña *et al.*, 1995, 1997; Gutiérrez *et al.*, 1997; Bond and Roose, 1998; Cervera *et al.*, 1998; Luth and Moore, 1999; Domínguez *et al.*, 2000; Yang *et al.*, 2000; Costa *et al.*, 2002; Yu *et al.*, 2002; Almeida *et al.*, 2003; Kayim *et al.*, 2004; Kayim and Koc, 2005). Of these, Luth and Moore (1999) reported the first successful grapefruit transformation using epicotyl segments. A CTV untranslatable coat protein gene (*uncp*) and the *Galanthus nivalis* agglutinin gene (*Gna*), a plant-derived insecticidal gene, were the first agronomic traits to be successfully transferred into a commercially important grapefruit variety, “Rio Red”, with the aim of improving resistance to CTV and to the aphids that transmit the virus (Yang *et al.*, 2000). Since this time, hundreds of transgenic grapefruit plants have been generated by several research programs employing the stated protocol, utilizing several grapefruit cultivars and numerous target genes.

For the selection of transgenic tissue and buds, antibiotic resistance genes, most frequently neomycin phosphotransferase (*nptII*) as a selectable marker and the intron-inserted β -glucuronidase (UIDA) reporter gene as a scorable marker, have been used with *Agrobacterium* methodology. In *C. paradisi*, some of the commercially important grapefruit cultivars are seedless (zero to five seeds per fruit), including “White Marsh”, “Ruby Red”, “Rio Red”, and “Star Ruby” as well as some other commercial sweet oranges, which make it more difficult to obtain adequate nucellar seedling explants for *Agrobacterium*-mediated transformation (Fleming *et al.*, 2000). The *Agrobacterium*-mediated transformation system is best suited for highly nucellar seedy citrus genotypes, but also works for low-seeded nucellar cultivars if abundant fruit is available, including the mentioned low-seeded grapefruit cultivars (Bond and Roose, 1998; Gonzalez-Ramos *et al.*, 2005; Ananthakrishnan *et al.*, 2007). This limitation in citrus transformation can also be overcome for some cultivars

by using a protoplast transformation system with a nondestructive selection system (Niedz *et al.*, 1995; Fleming *et al.*, 2000). Currently, protoplast transformation systems with green fluorescent protein (GFP) reporter gene have been used by Grosser and his coworkers in a few different citrus species (Fleming *et al.*, 2000; Olivares-Fuster *et al.*, 2003; Albiach-Marti *et al.*, 2004; Guo *et al.*, 2005). The protoplast transformation methodology provides some advantage over other methods by eliminating antibiotic selection and the use of antibiotics, which is now considered by some consumer groups to be a negative trait, and may preclude marketing in some markets, particularly in Europe. This protocol may also be useful for cultivars not susceptible to *Agrobacterium* infection or that exhibit inefficient plant regeneration via adventitious shoot–bud induction from stem or epicotyl segments after antibiotic application (Fleming *et al.*, 2000). Although grapefruit regenerates from embryogenic cultures, successful protoplast transformation has not yet been demonstrated.

2. PROTOCOLS FOR PRODUCING TRANSGENIC GRAPEFRUITS

All examples of transgenic grapefruit in the literature were by standard *Agrobacterium*-mediated transformation of nucellar seedling stem pieces similar to the following protocols.

2.1 Plant Material

Seeds are obtained by extraction from harvested fruit (or from commercial supplier), the outer seed coat peeled, and surface sterilized for 15 minutes in a 20% solution of commercial bleach. These seeds are then rinsed with sterile water three times (5–10 min each rinse). Following the rinsing, two seeds are placed per glass tube containing seed germination medium. The tubes are sealed with Nescofilm and incubated in the dark at room temperature ($25 \pm 4^\circ\text{C}$) for 5 weeks. During this period, seedlings will germinate from the seeds and grow to be about 10–12 cm long. Stems of etiolated plants are cut into 15–20 mm segments, placed into liquid co-cultivation medium (CCM), and subsequently into *Agrobacterium* suspension.

Alternatively, stems can also be obtained from germinated *in vitro*-grown somatic embryos (Luth and Moore, 1999).

2.2 Transformation and Regeneration

The explants are incubated in *Agrobacterium* suspension of appropriate optical density (OD) for anywhere from 2 to 15 min, blot dried, and put on plates with agar-solidified CCM. Plates are sealed and placed in the incubator for 2 days ($25 \pm 4^\circ\text{C}$). After this period, explants are transferred from plates with CCM to either regeneration medium (RM) or DBA3 regeneration media supplemented with 333 mg l^{-1} Cefotaxime (and/or carbencillin) to kill *Agrobacterium*, and appropriate antibiotic for selection (usually $50\text{--}70 \text{ mg l}^{-1}$ kanamycin), and left in the incubator for about 5 weeks. Recently, the transformation efficiency of “Rio Red” grapefruit was improved by including a shoot elongation phase with a liquid medium overlay, which eliminated problematic nontransgenic escape shoots (Yang *et al.*, 2000). Thirty-five days after co-incubation with *Agrobacterium*, shoots are harvested and tested for the presence of the reporter gene. CCM contains $1\times$ Murashige and Skoog salts and vitamins with 30 g l^{-1} of sucrose plus 3 mg l^{-1} of 6-benzyl adenine (BA), 0.1 mg l^{-1} of α -naphthalene acetic acid (NAA) (0.1 ml of NAA stock solution), 0.5 mg l^{-1} of 2,4-D, and 19.6 mg l^{-1} of acetosyringone. RM includes $1\times$ Murashige and Skoog salts and vitamins with 30 g l^{-1} of sucrose plus 3 mg l^{-1} of BA, 0.5 mg l^{-1} of NAA, plus appropriate antibiotics (i.e., 333 mg l^{-1} of Cefotaxime). DBA3 medium consists of $1\times$ Murashige and Tucker salts and vitamins with 25 g l^{-1} of sucrose plus 3 mg l^{-1} of BA, 0.01 mg l^{-1} 2,4-dichlorophenoxy-acetic acid, 1.5 g l^{-1} malt extract, and 20 ml l^{-1} coconut water (then add appropriate antibiotics) (Deng *et al.*, 1992). Alternatively, though with lower efficiency, transformation can be accomplished with selection on media containing hygromycin (Costa *et al.*, 2002).

2.3 *Agrobacterium* Culture

Most frequently used strains of *Agrobacterium tumefaciens* for transformation of grapefruit are EHA101, EHA105, and C58C1. *Agrobacterium*

cultures are grown in yeast extract peptone (YEP) medium and suspensions used for incubation of explants set to an optical density OD_{620} of 0.5–1. These strains can also be independently transformed by electroporation with the different pBin35GUS constructs along with the helper plasmid pCH32 containing additional copies of the *virG* gene for enhancing transformation efficiency (Ghorbel *et al.*, 2001). *Agrobacterium* has a natural transformation system that produces mostly single insertions in the citrus plant genome, therefore, seemingly avoiding gene silencing defense mechanisms in the targeted plants. EHA105 was shown to be twice as efficient as C58C1 in transformation of “Ruby Red” grapefruit (and “Hamlin” sweet orange) by Eric Mirkov and coworkers (Eric Mirkov, pers. comm.). This specificity for transformation demonstrated that, among so many variables involved in transformation experiments, the bacterial genotype is a variable that can be optimized.

2.4 Tests for Reporter Genes

Most frequently used reporter genes are the gene for β -glucuronidase (GUS) and GFP. GUS tests are performed in 96 well microassay plates. A complete, thin cross section is cut from the bottom of the shoot and dipped in 50 μ l of GUS assay solution that was aliquoted into individual wells. The plate sealed with Nescofilm is left at 37 °C for at least 4 h. Addition of 50 μ l of fixing solution to the tested sample results in bleaching of the tissue making it easier to score the shoots exhibiting blue staining. An example of a GUS-stained transgenic grapefruit shoot is provided in Figure 1(a). Examples of typical transformation efficiencies for various grapefruit cultivars are presented in Table 1.

To test for the presence of *gfp* as a reporter gene for transformation, shoots are observed under the “fluorescent” microscope, such as a Zeiss SV11 epifluorescence stereomicroscope equipped with a 100 W mercury bulb light source and a FITC/GFP filter set with a 480/30 nm excitation filter and a 515-mm-long pass emission filter (Guo *et al.*, 2005). As a result of the presence of GFP in transgenic tissue, shoots appear completely chartreuse green (Figure 1b), light pink, or red with green patches of different size. Under the same

Figure 1 Reporter gene expression in transgenic grapefruit: (a) Histochemical assay of GUS constitutively expressed in a transgenic apical portion of a citrus shoot after infiltration with X-Gluc substrate. (b) Transgenic (chartreuse green) adventitious shoot expressing GFP and nontransgenic escape adventitious shoot growing from stem explant

conditions, wild-type shoots (escapes) appear red due to chlorophyll fluorescence.

2.5 Growth of Transgenic Seedlings

Once the shoots have tested “positive” for the presence of reporter gene they can be elongated on BG elongation medium without kanamycin (Yang *et al.*, 2000) (optional) and then either placed on root-induction medium or used in micrografting onto rootstocks (usually sour orange, rough lemon, or Carrizo). Some of the shoots do not respond to root-induction media that typically have a high concentration of auxins (1–3 mg l⁻¹ NAA). To overcome this problem, transgenic shoots can be micrografted on rootstock seedlings *in vitro* (Peña *et al.*, 1995), with Carrizo being a good choice as transgenic shoots can easily be differentiated from adventitious Carrizo shoots exhibiting trifoliate leaves. Rooted seedlings and micrografted plants are grown for an additional 2–4 weeks under conditions of high humidity and then acclimated to a greenhouse environment.

2.6 Molecular Analyses

2.6.1 Southern blot analysis

Plant genomics is rapidly moving toward a more integrationist, rather than reductionist perspective, thereby increasing emphasis on gene identification

Table 1 Average transformation efficiencies from various grapefruit (+) *Agrobacterium*-mediated transformation experiments, calculated as the total number of GUS positive regenerated shoots/total number of inoculated explants. The percentage of GUS (+) shoots is calculated as the number of shoots staining blue divided by the number of shoots tested

(A) Comparison of two *A. tumefaciens* strains in two cultivars (transformation efficiency percentage)

At strains	Number of experiments	“Ruby Red” (mean \pm s)	“Hamlin” (mean \pm s)
C58C1	4	2.6 \pm 1.1	1.4 \pm 0.4
EHA105	2	5.4 \pm 2.7	3.7 \pm 0.6

(B) Average citrus cultivar susceptibility to transformation by *A. tumefaciens*

Cultivar	Number of experiments	Transformation efficiency (%) (mean \pm s)
Ruby Red	6	3.5 \pm 2.1
Rio Red	3	1.8 \pm 0.9
Hamlin	5	2.8 \pm 1.3

(C) Transformation with CTV-392 sequence (EHA105 + pTLAB14)

Cultivar	Number of explants	Number of shoots	Percentage of GUS (+) shoots	Transformation efficiency (%)	Whole plants recovered
Flame	790	814	13.33	0.49	4
Marsh	4220	3470	12.62	1.35	47
Ruby Red	1845	661	18.18	3.78	25
Duncan	1838	1722	10.67	0.64	11
All	8693	6667	13.08	1.30	87

(D) Transformation with CTV p23 (hairpin) sequence (EHA101 + pTLAB10) for different cultivars of grapefruit

Cultivar	Number of explants	Number of shoots	Percentage of GUS (+) shoots	Transformation efficiency (%)	Whole plants recovered
Flame	2647	787	28.09	2.67	21
Marsh	2166	446	25.43	3.36	15

and functional expression of novel proteins. To achieve this goal, genomic DNA from plants “positive” for the presence of the reporter gene (selected as an independent transgenic event) can be extracted, and 15 μ g of DNA is then digested with the appropriate restriction enzyme. A DNA-labeled probe can then be used in order to confirm the number of stable insertions of the transferred T-DNA fragment likely containing the gene of interest (see Figure 2 for an example). The number of insertions in this Southern blot ranged from one to about eight insertions; however,

more than 70% were single-insertion events. This has been a consistent trend in most of the independent *Agrobacterium*-mediated grapefruit transformations studied to date.

2.6.2 Northern blot analysis

To determine the accurate transcription of the genes, total RNA can be extracted from young leaves of selected transgenic plants. Ten micrograms of total single-stranded RNA are then

Figure 2 Southern blot hybridization of genomic DNA extracted from young leaves of two commercial citrus cultivars transformed with two antimicrobial genes. Genomic DNA was digested with *Hind*III and hybridized fragments showed the insertion number. From left to right: “Hamlin” sweet orange transformed with the lysozyme and the *SoD2* genes, lanes 1–4 and 5–8, respectively. Lanes 9 and 10 are nontransgenic “Hamlin” sweet orange and the “Ruby Red” grapefruit, respectively. Lanes 11–13 is the grapefruit cultivar “Ruby Red” transformed with the lysozyme gene. Lanes 14–18 is “Ruby Red” transformed with the spinach defensin gene

electrophoresed in formaldehyde gels and blotted onto nylon membranes (Amersham-GE Healthcare). The membranes can be hybridized with the complete DNA sequence of the transgenes of interest. The labeled probes are generally derived from the total DNA length of the structural genes of interest (see Figure 3 for an example).

3. DEVELOPMENT OF TRANSGENIC GRAPEFRUIT PLANTS

Due to its *in vitro* vigor and high potential for organogenesis (adventitious shoot production), grapefruit is probably the easiest commercially important citrus scion to transform using *Agrobacterium* and has, therefore, been used in many studies. Most of the early works was done with the seedy “Duncan” cultivar for convenience, but

now more research is shifting to other cultivars including “White Marsh”, “Rio Red”, “Ruby Red”, and “Flame”. One can expect to see many more reports on grapefruit transformation in the next few years, especially with antimicrobial target genes, as researchers try to develop solutions to citrus canker and HLB, true threats to the grapefruit and sweet orange industries worldwide. Genetic transformation in citrus, especially with grapefruit, has progressed tremendously during the past few years. Numerous transgenic plants can be produced within a year using genes coding for important agronomic traits or traits that will facilitate identification of gene function or characterization of a corresponding protein. In the future, grapefruit could be a model citrus scion for transformation with new genes discovered by citrus genome mapping projects and for functional genomics studies in citrus. Below are some

Figure 3 Northern blot of total RNA extracted from transgenic citrus leaves and nontransgenic controls. The hybridized transcripts of “Hamlin” sweet orange transformed with the spinach defensin and lysozyme genes are shown in lanes 1–3 and 11–15, respectively. While the transcripts of the spinach defensin gene in transformed “Ruby Red” grapefruit are shown in lanes 6–10. The nontransgenic (NT) controls of “Hamlin” and “Ruby Red” are shown in lanes 4 and 5, respectively

examples of target genes successfully transformed into grapefruit to date.

3.1 Virus-derived Genes for CTV Resistance

A tremendous effort by several laboratories has been focused on the development of transgenic CTV resistance in grapefruit, using candidate sequences derived directly from various CTV isolates. Coat protein- or RNA-mediated resistance has been the target of most of these studies. Although hundreds of transgenic grapefruit plants have been produced from several cultivars, only a few “Duncan” and “Rio Red” transgenic plants are showing potential for CTV resistance based on CTV graft challenges and subsequent enzyme-linked immunosorbent assay (ELISA) analysis (G.A. Moore and T.E. Mirkov, unpublished data). A few transgenic “Marsh” grapefruit plants containing the 392-CTV sequence (containing part of p23 and the untranslated region (UTR) of CTV genome) showed altered replication in protoplasts with CTV virions based on Northern blot analysis (Ananthakrishnan *et al.*, 2007), but it has yet to be determined if this result has any value at the whole-plant level. Information on transgenic grapefruit plants and the CTV-derived target genes is summarized in Table 2.

3.2 Trifoliolate Orange Derived CTV Resistance

Most citrus species and cultivars are susceptible to CTV infection. However, the trifoliolate orange (*Poncirus trifoliata* L. Raf.), a sexually compatible relative of *Citrus*, has a single gene, named *Ctv*, which confers virtual immunity to CTV (Yoshida, 1993; Gmitter *et al.*, 1996). This gene can prevent viral proliferation *in planta* by an undetermined mechanism (phenotypically, ELISA results are negative), essentially resulting in host immunity. Since the development of the first localized linkage map of the *Ctv* locus (Gmitter *et al.*, 1996), substantial efforts have been devoted to clone it for use in transformation experiments aimed at developing CTV-resistant cultivars (Deng *et al.*, 2000, 2001; Yang *et al.*, 2000). The susceptible allelic region, *Ctv*, has also been sequenced and analyzed by Fred Gmitter’s group (unpublished data) and compared with the resistance allelic region. Analysis of the full-length genetic sequence of *Ctv* has revealed seven disease resistance genes belonging to the CC-NBS-LRR class, of which two contain a frameshift or internal stop codon. When compared with the susceptible allelic sequence, three of the remaining five genes have nearly identical sequences, but two others are clearly distinct from their susceptible allelic sequences (F. Gmitter, unpublished data). These two genes

Table 2 Transgenic grapefruit plants with candidate CTV-derived sequences for potential virus resistance (*gus* reporter gene used in all experiments)

are adjacent within 10kb and in opposite orientation. These two sequences have been their primary focus, as they were considered the most likely candidate CTV resistance gene(s) and have been designated as *Ctv.R5* and *Ctv.R6*. The ORF full length of *Ctv.R5* is 2700 bp, and *Ctv.R6* is 2670 bp.

3.2.1 Designing transgenes

Two binary vectors have been used for plasmid construction. The first binary Ti vector was derived from the assembly of pCAMBIA2301 with the *nptII* gene (under the 35S CaMV promoter and terminator) as the selectable marker and the 35S-*gus* gene (under the 35S CaMV promoter and nos terminator) as the reporter gene. *Ctv.R5* and *Ctv.R6* were inserted into the *Bam*HI site. The second binary Ti vector was derived from the assembly of pGreen0029 (provided by R.P. Hellens and P.M. Mullineaux) with the *nptII* gene (under the nos promoter and terminator) as the selectable marker (Hellens *et al.*, 2000) and the 35S-*gfp* gene (under the 35S CaMV promoter and terminator) as the reporter gene (Chen *et al.*, 2007). *Ctv.R5* and *Ctv.R6* were inserted in the *Spe*I site. These binary vectors were introduced into competent *Agrobacterium* AGL1 cells by electroporation.

3.2.2 Transformation and testing of regenerated plants

“Duncan” grapefruit was transformed as previously described using the *Agrobacterium* AGL1 strain harboring the binary vectors with *gus* as the reporter gene. Transgenic shoots regenerated from transformed epicotyl explants on selective medium were micrografted onto “Carrizo” seedlings *in vitro* (Peña *et al.*, 1995). After 6–8 weeks, these putative transgenic grafted plants were transferred to soil in liners. The leaves of the putative transgenic grafted plants were used for histochemical GUS assays or the *gfp* expression was observed with a fluorescent microscope Zeiss SV6. DNA was extracted from the putative transgenic grafted plants. Polymerase chain reaction (PCR) analysis was carried out using primers for *nptII*, *gus*, *gfp*, *Ctv.R5*, and *Ctv.R6* to verify the putative transgenic grafted plants. The transformation efficiency for pCAMBIA2301 containing *Ctv.R5*

and *Ctv.R6* genes was 1.88% and 1.54%, respectively. pGreen0029 containing *Ctv.R5* and *Ctv.R6* genes showed a transformation efficiency of 2.15% and 1.90%, respectively.

These transgenic plants have been grafted onto CTV-infected rootstocks to test the CTV replication by ELISA. However, the preliminary results have not been clear in confirming with certainty that either candidate alone is capable of inducing resistance to CTV. (Note: Similar results have been obtained via a collaborative effort by the groups of Eric Mirkov (Texas A&M) and Mikeal L. Roose (University of California, Riverside).

Hence, the possibility that both genes may be required for resistance is being explored. Studies have been carried out using two T-DNAs harbored in the same *Agrobacterium* strain either on different replicons (Daley *et al.*, 1998) or on the same replicon (Komari *et al.*, 1996) and used for co-transformation. Recently, a 1:1 mixture of AGL1 carrying the two binary vectors (one with *gus* as the reporter gene and the other with *gfp* as the reporter gene) separately was used to co-transform the epicotyl explants (Soneji *et al.*, 2007). This approach has resulted in some successful co-transformants, but they are still too small for graft inoculation challenges.

3.3 Virus-derived Genes for *Citrus* Psorosis Virus Resistance

In efforts to develop *Citrus* psorosis virus resistance, the entire viral coat protein (CP) gene was transferred into “Duncan” grapefruit, by the *Agrobacterium* method outlined above. Challenged independent transgenic lines did not show virus symptoms within the first 6 months. Some lines showed restricted symptoms around the graft inoculation site, suggesting there may be some level of resistance (Kayim *et al.*, 2005). However, a year later, transgenic plants developed characteristic symptoms of *Citrus psorosis virus* on the leaves of all challenged transgenic grapefruit plants (M. Kayim, unpublished data).

3.4 Spinach Defensin Gene (*SoD2*)

This gene construct encodes the tobacco PR-1 signal peptide for secretion, and *SoD2* is known

to be an antimicrobial peptide that affects the membranes of gram-positive and gram-negative bacteria. It is known to have broad-spectrum antimicrobial effects (Segura *et al.*, 1998; Lay and Anderson, 2005) and, therefore, has potential against both citrus canker and citrus greening.

3.4.1 Binary vector construction

SoD2 was cloned into binary plasmid pBin34SGUS, containing the selective *nptII* and *gus* genes for direct use in explant transformation (Yang *et al.*, 2000). The synthetic structural *SoD2* gene was obtained from W.O. Dawson's laboratory of the University of Florida's CREC. The structural gene sequence was optimized for citrus expression and contains the PR-1 signal peptide for protein secretion into the plant apoplast. This gene was cloned in pCR 2.1 TOPO vector (Invitrogen Corp., Carlsbad, CA) and digested with *EcoRI*. The 0.29 kb *EcoRI* fragment was inserted in the same restriction site of pRTL22 obtaining pRTL22/*SoD1* plasmid. Flanking the target gene were the double *Cauliflower mosaic virus* (CaMV) 35S promoter and the CaMV 35S terminus, upstream and downstream from the gene of interest, respectively. This functional gene sequence was digested with *HindIII* and inserted in the same unique site of pBin35SGUS plasmid vector. The newly produced DNA molecule was the vector pBin35SGUS/*SoD2* (Gonzalez-Ramos *et al.*, 2005).

3.4.2 Transgenic plant production

Populations of transgenic "Ruby Red" and "Rio Red" grapefruit plants containing the *SoD2* gene were produced. Transformation efficiency was approximately twofold higher for "Ruby Red" than "Rio Red", showing a genotype interaction.

3.4.3 Characterization of transgenic plants

3.4.3.1 Southern analysis to determine gene copy number

Genomic DNA was extracted from GUS positive plants, and 15 µg DNA from each independent

transgenic event was digested with the restriction enzyme *HindIII*. A GUS DNA labeled probe was used in order to confirm the number of stable insertions of the transferred T-DNA fragment likely containing the target gene (Figure 2). The number of insertions in these transgenic plants as determined by this Southern analysis ranged from about one to eight copies, with more than 70% being single insertions (a consistent trend in grapefruit transformation).

3.4.3.2 Northern analysis to verify transcription

Total RNA was extracted from young leaves of transgenic plants. Ten micrograms of total single-stranded RNA were electrophoresed in formaldehyde gels and blotted onto nylon membranes (Amersham-GE Healthcare). The membranes were hybridized with the complete DNA sequence of the target genes (*SoD2*, as well as Bovine Lysozyme gene described below). The labeled probes were derived from the total DNA length of the structural genes of interest. Results suggested that a large number of insertions in the plant genome increased the likelihood of a significantly reduced messenger RNA (mRNA) transcription or complete gene silencing. For example, a large number of insertions occurred in plants 419, 202, and 861, and the amount of mRNA accumulated in these same plants varied considerably (Figures 2 and 3). Thus, in Figure 3, it is shown that plant 419 was completely silenced; while plant 861, with a larger number of insertions compared to plant 419, produced some mRNA. On the other hand, plant 202, with a similar number of insertions as plant 861, produced substantially greater amounts of mRNA (Figure 3). In summary, large insertion numbers in the genome of transgenic plants make uncertain the products of plant transformation.

3.5 Bovine Lysozyme Gene (*BVLZ*)

This gene is a member of the bacteriolytic enzymes found in nature. It also provides broad-spectrum antimicrobial resistance and could be effective against citrus canker or greening. The construct maintains its native signal peptide while the AUG

start codon context has been optimized to improve expression levels in plants.

3.5.1 Binary vector construction

A similar strategy as outlined above for *SoD2* was utilized.

3.5.2 Transgenic plant production and analyses

As with *SoD2*, populations of transgenic “Ruby Red” and “Rio Red” were produced.

3.5.2.1 Southern and Northern analyses

Both were conducted as described above for *SoD2*.

3.5.2.2 Transgene expression

To investigate the level and stability of expression of *BVLZ*, total leaf proteins were isolated from transgenic plants. The complex mixture of proteins was separated by SDS-PAGE and blotted onto a nitrocellulose membrane (Amersham) by electroblotting. The membrane was probed with a polyclonal primary antibody (rabbit anti-BVLZ serum), and goat antirabbit IgG (Fc) alkaline phosphatase conjugate as a secondary antibody. This system allowed the indirect visualization of the BVLZ protein (Figure 4). The secondary antibody was detected in about 90% of the transgenic plants tested for the level of protein

accumulation. The variation in the amount of protein expressed on the immunoblot appears to be associated with the amount of transcription of the gene of interest (data not shown).

3.5.2.3 Validating the antimicrobial recombinant proteins *SoD2* and *BVLZ* against asiatic citrus canker (*Xac*) in Florida

In the summer of 2005, under appropriate permits, transgenic budwood was shipped from Texas A&M to the laboratory of J.H. Graham at the University of Florida. Transgenic plants were assayed using a virulent isolate of *Xac*. Transgenic and nontransgenic plants were inoculum infiltrated on the abaxial surface of young expanding leaves with a 10^4 CFU ml⁻¹ bacterial suspension as explained by Vilorio *et al.* (2004). Preliminary results indicated that at least one of the transgenic events in the “Rio Red” cultivar, expressing the *SoD2* gene, has shown resistance to artificially inoculated *Xac* (Figure 5). The quantitative variables of bacterial count and lesion number per inoculation site are known to be correlated (Vilorio *et al.*, 2004). Therefore, based on lesion number, the susceptible nontransgenic “Rio Red” developed five times more lesions per inoculation site as compared to the resistant transgenic “Rio Red” counterpart expressing the *SoD2* gene (Figure 5a). It is shown in Figure 5(b) that only one insertion of the cassette containing the *SoD2* gene occurred in the genome of “Rio Red” transgenic resistant plant number 5. The Northern blot shown in Figure 5(c) provides evidence of the amount of mRNA produced by this resistant transgenic event in “Rio Red”.

Figure 4 Western blot of total proteins extracted from young citrus leaves. From left to right: Lane 1 shows the protein size marker. Lanes 2–5 are transgenic “Ruby Red” expressing the BVLZ, except event 968. Event N87 is the citrange “Carrizo” used as a positive control. Lane 8 is a “Rio Red” transgenic event, and lines 9 and 10 are Hamlin events also expressing the lysozyme protein

Figure 5 Artificially inoculated leaves of transgenic and nontransgenic "Rio Red", Northern and Western blots showing the insertion copy number and the constitutive mRNA expression of the *SoD2* gene. (a) Level of resistance produced by the transgenic plant event 5 containing the spinach defensin gene in the elite cultivar "Rio Red" compared to the nontransgenic control of the same grapefruit cultivar. (b) Southern blot analysis of the transgenic "Ruby Red" plant 53 and the transgenic "Rio Red" plants 5 and 6. (c) Western blot showing the amount of mRNA produced by the same plants with the transgenic events 53, 5, and 6

3.6 Biosynthetic Genes

Genes from the carotenoid biosynthetic pathway cloned into pCAMBIA2301 were successfully transferred to "Duncan" grapefruit using the standard *Agrobacterium*-mediated protocol described earlier. Transgenes included lycopene- β -cyclase, phytoene desaturase, and phytoene synthase, all under the control of constitutive promoters. All three vectors had the *nptII* selection gene and *gus* as a reporter. Transgenic plants were confirmed by PCR and Southern blot analysis (Costa *et al.*, 2002). Further characterization of these transgenic plants awaits field evaluation and fruiting after a long period of juvenility. This group also attempted transformation with BIBAC vectors in efforts to transform with larger T-DNA inserts. Unfortunately, these experiments resulted in poor shoot morphogenesis and no transgenic plant recovery.

4. FIELD EVALUATION OF TRANSGENIC TREES IN SOUTHERN TEXAS

Under appropriate USDA permits, the Texas A&M Agricultural Experiment Station in Weslaco (TAES) has the only field-grown transgenic grapefruit trees, which are expressing the *uncp* and *Gna* genes. These trees have been under observation, and the first preliminary data based on histological activity of the *gus* gene in endosperm and fruit rind, and fruit size and color, and quality as indicated by the total soluble solids in the fruit are shown in Table 3 and Figure 6.

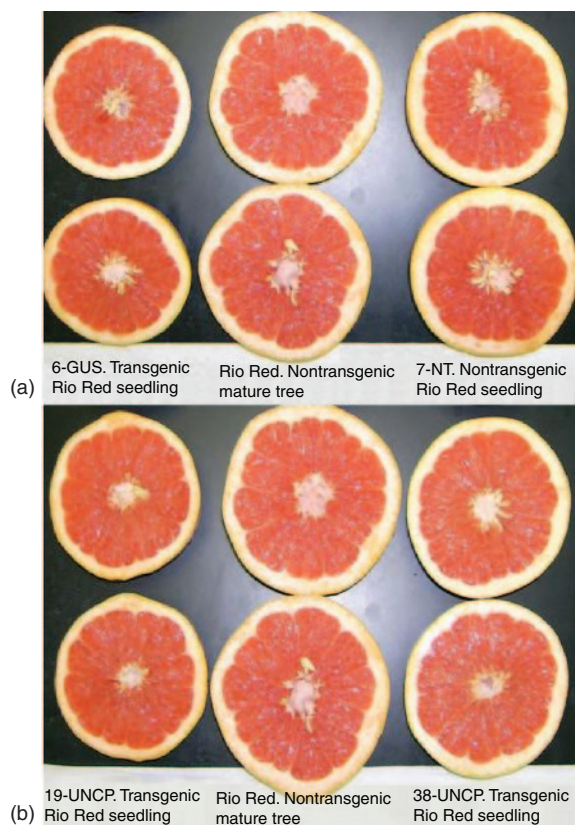

The Brix degrees were similar within the transgenic fruits and no different to the nontransgenic seedling fruits. GUS activity showed variations that probably could be explained in part by the natural level of expression and random variation. Within the transgenic group, fruits showed similar

Table 3 Number of fruits, seeds, and Brix degrees of transgenic “Rio Red” harvested at TAES-Weslaco 6 years after seedling trees were planted in the field

Tree and gene	Fruit number	Total seed number	Brix degrees (mean \pm s)	GUS activity
4-GUS	1	1	10.5	+
6-GUS	3	8	9.20 \pm 0.17	—
7-NT ^(a)	9	23	9.48 \pm 0.49	—
19-UNCP	8	20	9.45 \pm 0.40	+++++
27-UNCP	1	2	9.40	++++
38-UNCP	2	5	9.35 \pm 0.07	+++++
64-UNCP	3	5	9.83 \pm 0.38	+++
Rio Red-NT ^(b)	5	NA	11.6 \pm 0.05	—

^(a)Nontransgenic seedling^(b)Nontransgenic mature tree

size and color. The larger size of the nontransgenic fruit shown in Figures 6(a) and (b) is mainly due to the fact that this fruit was harvested from a mature tree.

**Figure 6** “Rio Red” fruits transgenic for GUS and UNCP. (a and b) Fruits 6-GUS, 19-UNCP, and 38-UNCP expressing their respective transgenes were harvested from transgenic seedlings. Fruit 7-NT is from a nontransgenic seedling. The fruit of nontransgenic “Rio Red” is from a mature tree

1. INTRODUCTION

Bananas and plantains (*Musa* spp.) are the world's fourth most important food crop after rice, wheat, and maize in terms of gross value of production, with the vast majority of the crop grown and consumed in the tropical and subtropical zones. They provide a staple food for millions of people, particularly in Africa, an area where the green revolution has had little influence.

The performance of bananas and plantains can be severely affected by diseases and pests, including black Sigatoka (*Mycosphaerella fijiensis*), *Fusarium* wilt (*Fusarium oxysporum* f. sp. *cubense*), bacterial wilt (*Xanthomonas campestris* pv. *musacearum*), viruses (banana bunchy top virus, banana streak virus), nematodes, and weevils. These pest and diseases can cause economically significant food and income losses. Consequently, the largest single component in the cost of production of dessert banana and plantain in the tropics is disease control. Current control measures, which vary from cultural and biological to chemical control, comprise approximately 40% of total production cost (Ganry, 1993). Bananas and plantains are predominantly smallholders' crops; most growers cannot afford costly chemicals to control pests and diseases. This leaves host plant resistance as the most sustainable approach to counteracting pest and disease pressure, both under small-scale and

large-scale banana and plantain production schemes. Banana and plantain present many challenges for genetic improvement, notably associated with the reproductive biology, the complexity of trait expression, and the long generation time of the crop. Transgenic technology, together with conventional methods can assist in overcoming these problems in developing improved cultivars of banana and plantain.

1.1 History, Origin, and Distribution

Bananas and plantains are giant herbs that belong to the Musaceae, one of the six families of the order Zingiberales. The Musaceae have been associated with human history for a long time (Rowe and Rosales, 1996). The banana plant has been described as the "Tree of Paradise" in the Koran and as the "Tree of Knowledge" in the Book of Genesis in the Old Testament, hence the earlier taxonomic identification of bananas as *Musa paradisiaca* L. or *M. sapientum* L., which some authors still use nowadays.

The cultivation of bananas was first documented in ancient scriptures of India dating back to 500–600 BC (Reynolds, 1927). However, there is mounting archaeological evidence in support of earlier cultivation in Papua New Guinea, at least 7000 years ago and possibly as far back as 10 000 years ago (Denham *et al.*, 2003). Thus,

the New Guinean highlands would be the place where bananas were first domesticated. Organized plantation of bananas existed in China in 200 AD, four centuries before Islamic conquerors brought the banana to Palestine, and Arab merchants eventually spread the plant over much of Africa. The word *banana* is of West African origin, but it is derived from the Arabic *banaan* (finger), and passed into English via Spanish or Portuguese. However, the long debated when and by what routes *Musa* (bananas) were introduced to tropical Africa and South America remain unresolved.

Cultivated bananas and plantains are predominantly triploid ($2n = 3x = 33$) female-sterile varieties that evolved from two diploid ($2n = 2x = 22$) seminiferous species, *Musa acuminata* Colla (genome AA) and *Musa balbisiana* Colla (genome BB), originating from the tropical Malay region and the Northern Indian region, respectively (Simmonds, 1962).

It is hypothesized that the evolutionary pathway leading to the emergence of cultivated varieties from the seminiferous ancestors comprised two critical events, both of which occurred in Southeast Asia, the center of origin and primary diversity of bananas. Firstly, vegetative parthenocarpy and female sterility appeared in *M. acuminata*, allowing for production of pulp without seeds as evidenced by the occurrence of parthenocarpic and seedless diploid *M. acuminata*. Secondly, crosses within *M. acuminata* or between *M. acuminata* and *M. balbisiana* occurred, facilitated by female restitution and haploid fertilization, and produced two groups of natural hybrids. One group comprises autopolyploid and homogenomic hybrids that are essentially AAA dessert and East African Highland bananas. The other group contains allopolyploid and heterogenomic types: the AAB plantains and starchy bananas and the ABB cooking bananas.

The natural hybrids do not produce seeds and can only reproduce by vegetative propagation, implying that survival in nature and geographical dispersal could not occur without human intervention. Therefore, it is widely accepted that secondary diversification in areas devoid of wild *Musa* plants, e.g., Western and Central Africa, must be due to somatic mutations of a small number of introduced materials, rather than through multiple introductions (De Langhe *et al.*, 2005).

In Africa, the cultivars are usually known under a multitude of vernacular names, superimposing linguistic diversity to genetic and ecological diversity of the varieties in any given area (Rossel, 1998). Similar interactions between linguistics and genecology occur throughout Asia, the geographical origin and primary diversification center of the *Musaceae*. Thus, a good understanding of demographic history and dispersal mechanisms may help explain the structure of genetic diversity among populations of bananas and plantains across geographical regions.

1.2 Botanical Description

The taxonomy of bananas and plantains has attracted many excellent treatises that also describe the distinguishing features among cultivated forms (Simmonds, 1962; Stover and Simmonds, 1987; Robinson, 1996; De Langhe *et al.*, 2005). Baker (1893) was first to establish a formal classification of the genus *Musa*. He recognized three subgenera: *Physocaulis* (wild and inedible seeded bananas), *Eumusa* (species with edible fruits), and *Rhodochlamys* (inedible fruits and brightly colored bracts). Baker's classification was revised by Cheesman (1947) whose detailed taxonomic treatment was based primarily on chromosome number, pseudostem stature, inflorescence characters, and seed morphology. Cheesman adopted the concept of sections or series at the subgeneric level, dividing the genus *Musa* into *Eumusa* ($x = 11$), *Rhodochlamys* ($x = 11$), *Australimusa* ($x = 10$), and *Callimusa* ($x = 10$). The majority of the cultivated bananas belong to the section *Eumusa*. This section is the biggest in the genus and the most geographically widespread with species found throughout Southeast Asia from India to the Pacific Islands.

Cheesman's classification is still widely accepted, despite subsequent reports of basic chromosome numbers of 7 for *Musa ingens* and 9 for *Musa beccarii* (Shepherd, 1959) or the discovery of *M. ingens* that could not be fitted to any of the sections (Argent, 1976). In fact, several unresolved issues remain, including the evolutionary relationships among the four sections of the genus *Musa*, the separation of sections *Eumusa* and *Rhodochlamys* with apparently little taxonomic support, and the relationship between

the wild progenitors and the cultivated clones (Shepherd, 1999).

It is now accepted that the diversity of bananas in the wild has not been exhaustively described and classified, with new information prompting taxonomic revision from time to time at the species level, and more rarely, at the genus level (Valmayor and Danh, 2002; Häkkinen, 2006).

Ploidy and genome configurations have played a determinant role in the classification of bananas, with major groups including diploids (AA, BB, AB), triploids (AAA, AAB, ABB), and tetraploids (AAAA, AAAB, AABB, ABBB). There is wide consensus about the attributes conferred by A or B genomes in interspecific natural or artificial hybrids of *M. acuminata* and *M. balbisiana*. Hence, it is accepted that edibility of mature fruits arose from mutations causing parthenocarpy and female sterility in diploid *M. acuminata* (Simmonds, 1962). It is equally accepted that hardness is contributed by the B genome since *M. balbisiana* clones thrive abundantly in areas experiencing pronounced dry seasons alternating with monsoons. Also attributed to the B genome are fruit characteristics, such as starchiness and acid taste, causing AAB plantain to be starchier but less sweet and less palatable when raw than the AAA dessert bananas (Simmonds, 1962).

The African plantains (AAB) display greater variation than any other subgroup of triploid bananas in the world, with morphological variation occurring for inflorescence type, plant size, fruit orientation, fruit shape, pseudostem, and fruit color. Based on inflorescence morphology, four types have been distinguished, namely, French plantain, French Horn plantain, Horn, and False Horn plantain, which are further divided into giant, medium, and small types.

While various combinations of the A and B genomes predominate in most cultivars, two other genomes, denoted as S (from *M. schizocarpa*) and T (from *M. textilis*), occur albeit in a few accessions. Thus, genomic groups with the S genome include AS, AAS, and ABBS while those with the T genome are AAT, AAAT, and ABBT (Sharrock, 1990).

Pillay *et al.* (2004) provided a succinct review of studies on genome size and cytological features of bananas. Relatively few studies have been conducted in *Musa* to determine genome size, with large differences in the DNA content estimates

obtained by different authors (Lysak *et al.*, 1999; D'Hont *et al.*, 2000; Kamaté *et al.*, 2001). Thus, DNA content ranging from 1.11 pg $2C^{-1}$ to 1.33 pg $2C^{-1}$ was reported for diploid *M. acuminata* accessions. Likewise, nuclear DNA content ranging from 1.03 pg $2C^{-1}$ to 1.16 pg $2C^{-1}$ were found for diploid *M. balbisiana*, while S and T genomes were reported to contain 1.18 pg $2C^{-1}$ and 1.27 pg $2C^{-1}$ DNA, respectively. Clearly, additional research may be needed before robust comparisons of DNA content in the A, B, S, and T genomes can be made, prompting Pillay *et al.* (2004) to advise that caution be exercised in interpreting DNA content data in *Musa*.

1.3 Economic Importance

Banana and plantain are important cash and subsistence crops in most tropical and subtropical regions of the world, growing on production cycles of 12–18 months, essentially as perennial crops that can be harvested all year round (Robinson, 1996). Almost all banana and plantain cultivation falls within 30° latitude north and south of the equator (Stover and Simmonds, 1987). They require an average temperature of about 30 °C and a minimal rainfall of 100 mm per month (Swennen and Rosales, 1994). These crops are cultivated on approximately 10 million ha worldwide with an annual production exceeding 100 million metric tons, which are distributed among Africa (40%), Asia (30%), Latin America, and the Caribbean (30%).

As mentioned above, the existing cultivars are assigned to three genome groups, AAA, AAB, and ABB but varieties grouped in the same genomic category can be very dissimilar (Simmonds, 1962; Stover and Simmonds, 1987; Robinson, 1996). Thus, the AAA group contains sweet dessert bananas that are eaten raw when ripe and bananas of the East African highlands that require cooking before they can be eaten or brewing before drinking. Likewise, the West African and Asia Pacific (Maia maoli/Popoulou) plantains that are cooked before eating dominate the AAB group, which also contains dessert bananas of the Pome subgroup. Varieties in the ABB group are essentially used for cooking, but some may be eaten raw as dessert bananas usually when overripe.

Economically, bananas and plantains constitute major export crops in some countries

predominantly in Latin America and the Caribbean and a few countries in Western and Central Africa. However, only about 10% of world production, predominantly AAA dessert bananas of the Cavendish type, enters international trade. The bulk of the production provides an important staple food for rural and urban consumers in the production areas where bananas and plantains also constitute an important source of income for rural populations.

Bananas and plantains are the major staple food in the equatorial belt of Africa, where more than 70 million people derive in excess of 25% of their daily calorie intake from plantains in West and Central Africa (Robinson, 1996). Indeed bananas are rich in carbohydrates (about 35%) and fiber (6–7%), and have a relatively low protein and fat content (1–2%), and constitute a good source of major elements, such as potassium, magnesium, phosphorus, calcium, iron, and vitamins A, B6, and C (Marriott and Lancaster, 1983). Bananas play a vital role in the nutrition and well-being, and cultural life of millions of people in Central and Western Africa and South and Central America, often being the first solid food for infants (Price, 1995).

Bananas and plantains can be processed into a variety of secondary products from fibers to wrappings and are fermented to produce alcohol. However, these options are essentially practiced at rudimentary scales, despite their potential for industrial production.

1.4 Traditional Breeding

Banana and plantain were introduced in Africa only about 3000 years ago (De Langhe, 1995) and a remarkable diversity now exists for both groups, but all traditional varieties have become susceptible to a range of pests and diseases, the most serious of which are black Sigatoka (*Mycosphaerella fijiensis* Morelet), Fusarium wilt (*Fusarium oxysporum* f. sp. *cubense*), banana weevil (*Cosmopolites sordidus* Germar), and a complex of plant parasitic nematodes (*Pratylenchus goodeyi*, *Helicotylenchus multicinctus*, and *Radopholus similis*). Therefore, breeding efforts focus on developing new disease and pest resistant varieties that also retain the organoleptic properties of the traditional varieties.

There are two basic steps in plant breeding: (a) accessing natural variation or artificially creating

genetic diversity, and (b) selecting individuals with the desirable gene combinations from existing or artificially created populations. These principles have been applied for seed-propagated crop species using techniques that are often referred to as conventional. However, a commonly held view is that the most widely used so-called conventional or classical plant breeding techniques from sexual, seed-propagated crops are not appropriate for banana and plantain improvement. The distinction between “conventional” and “non-conventional” breeding lies in the methods of gene shuffling and in the origin of the genes being manipulated. Nevertheless, the methodological principles applied for sexually propagated crops can be, and have been, applied to banana and plantain breeding, with the aid of nonfield methods of recovering viable progeny and identifying those progenies with putatively desirable gene combinations. In this regard, there is nothing conventional about banana and plantain breeding (Tenkouano, 2005).

Banana and plantain breeders aim to produce seedless varieties, preferably in the triploid ($3x$) background common to the majority of existing cultivars. This usually involves crossing $3x$ cultivars to diploid ($2x$) accessions that are donors of resistance genes, selecting $4x$ and $2x$ primary hybrids from the $3x - 2x$ progenies, and crossing $4x - 2x$ hybrids to produce secondary $3x$ hybrids. Alternatively, secondary $3x$ hybrids may be produced via $2x - 2x$ crosses where one of the $2x$ parents produces $2n$ pollen. However, this requires screening of diploid lines for $2n$ pollen production, and setting crossing schemes that would allow pollination to coincide with periods that are favorable for $2n$ pollen production.

Other methods of producing triploid hybrids have been explored, such as tetraploidization of diploid accessions using colchicine prior to crossing with another diploid (Tézenas du Montcel *et al.*, 1996). Colchicine prevents the formation of mitotic spindles, resulting in mitotic restitution in treated cells. This technique may preserve advantageous linkages selected at diploid level, particularly in the tetraploid derived from the diploid, but recombination can occur when crossing the tetraploid with a diploid to produce a triploid, with the potential of disrupting linkages. Also, colchicine treatment may not affect uniformly all cells in multicellular meristems, causing

cytochimeras that may not be easy to dissociate (Roux *et al.*, 2001). Thus, efficient methods for *in vitro* dissociation of chimeras and selection of the desired cells are required, before such cells can be cultured to regenerate a plant that will now be used for crossbreeding. Furthermore, the use of colchicine can cause increased inbreeding, reduced vigor, and reduced genetic variability (Ortiz *et al.*, 1992). Thus, colchicine-mediated polyploidization is impractical for routine breeding operations in plantain and banana.

Hence, tetraploid \times diploid crosses remain the predominant triploid breeding scheme, although the multiploidy and heterogenomic structure of breeding populations results in unpredictable variation in genome size and structure across and within generations. This causes complex inheritance patterns and complicates phenotypic selection for most yield and growth traits (Ortiz and Vuylsteke, 1996).

Despite these limitations, many improved hybrids combining genetic resistance to black Sigatoka with appropriate agronomic characteristics have been developed (Swennen and Vuylsteke, 1993; Ortiz and vuylsteke, 1998). The improved hybrids are about two to five times more productive than the traditional plantain landraces, under natural conditions with no chemical control of black Sigatoka. These hybrids are now being introduced into farmers' fields in several countries, across Africa (Gallez *et al.*, 2004; Tenkouano and Swennen, 2004) with relatively high adoption prospects (Tenkouano *et al.*, 2006).

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

A good understanding of the structure of diversity in the existing materials is required to access natural variation or to artificially create genetic variation. Early breeders relied essentially on morphological and geographical information, which may not be adequate. Recent advances in the development of molecular or cytological tools stand to benefit modern breeders, notably by clarifying phylogenetic relationships, thus allowing for inferences about gene pools. For example, amplified fragment length polymorphism analysis of total DNA revealed that the *M. acuminata* complex of about 50 morphological subspecies

can be ascribed to only three genetic subspecies (*burmannica*, *malaccensis*, and *microcarpa*) while *M. balbisiana* was shown to contain two forms (Singapuri, I-63), suggesting that there might be at least three A genomes and two B genomes (Ude *et al.*, 2002a, b). Furthermore, it seems that the A genomes in the plantains come from the subspecies *microcarpa* while the B genome comes from the I-63 form of *M. balbisiana*. More recently, Ge *et al.* (2005) also traced variation in *M. balbisiana* to two main clades, based on simple sequence repeat length polymorphisms and CpDNA analysis. Such information becomes important when attempts are made to diversify and broaden the genetic foundation of breeding populations, particularly in the search for novel genes.

In fact, as new genomic resources become available, or are applied in conjunction with cytogenetic tools (Bartos *et al.*, 2005) or numerical tools (De Langhe *et al.*, 2005), the taxonomic description of the *Musaceae* will likely evolve. These findings have major implications for evolutionary or reconstructive breeding, aiming to re-enact existing landraces without some of their shortcomings such as disease susceptibility.

Despite these advances, many problems specific to the biology of plantains and bananas impede rapid breeding progress, including low reproductive fertility, triploidy, and slow propagation (Vuylsteke *et al.*, 1997). Thus, breeders may not be able to access all available variation, largely due to the high sterility of many cultivated varieties; the conundrum of banana breeding is that seed set is required to produce seedless varieties. Improving female or male sterile accessions can only be achieved by circumventing reproductive barriers, e.g., by deliberate mutagenesis or by direct gene transfer through genetic engineering.

The crossbreeding approach is time consuming, given the long generation time of the crop and it is also technically complex, since it requires both ploidy and genome selection. With the advent of flow cytometric analysis of nuclear DNA content (Dolezel, 1997) and molecular markers for the A and B genomes (Pillay *et al.*, 2000), ploidy and genome selection have become easier. However, predicting progeny performance remains a major challenge when ploidy and genome variation occurs within and across generations (Tenkouano *et al.*, 1999a, b). Ideally, genetic engineering would provide a more deterministic approach

for substituting undesirable genetic materials with those that would enhance the performance of the recipient line or cultivar with respect to a particular constraint.

Additionally, the available germplasm may not harbor the desired genes with respect to an emerging threat, which is clearly the case for the bacterial wilt caused by *X. campestris* pv. *musacearum* that is threatening livelihoods in the Great Lakes region of central and eastern Africa. There is little that crossbreeding can do to address such a threat in the near future, leaving genetic engineering as the best alternative to control the bacterial wilt epidemics through host resistance.

Genetic engineering could target the development of improved versions of existing cultivars for deployment or, alternatively, insert alien resistance genes into breeding lines for later use in crossbreeding schemes.

2. DEVELOPMENT OF TRANSGENIC BANANAS AND PLANTAINS

In view of the constraints of conventional breeding in banana and plantain already mentioned, the case for using transgenic approaches to improve these crops is particularly compelling. Because of the lack of cross-fertile wild relatives in many banana producing areas, as well as the male and female sterility of most edible bananas and plantains and the clonal mode of propagation, gene flow is not an issue for this crop, making a transgenic approach even more attractive.

Genetic transformation has become an important tool for crop improvement. Genetic engineering, i.e., the introduction and stable integration of genes into the nuclear genome and their expression in a transgenic plant offers a better alternative for the genetic improvement of cultivars not amenable to conventional crossbreeding, such as Cavendish bananas and False Horn plantains (Jones, 2000). The successful genetic transformation in plants requires the production of normal, fertile plants expressing the newly inserted gene(s). The process of genetic transformation involves several distinct steps, namely, identification of useful gene, the cloning of the gene into a suitable plasmid vector, delivery of the vector into plant cell (insertion and integration) followed by

expression, and inheritance of the foreign DNA encoding a polypeptide. With the advent of plant biotechnology and the rapid development of gene transfer techniques, the potential to introduce desirable traits is no longer restricted to those occurring in close relatives. In theory, genes, once identified, isolated, and cloned may be introduced to a plant from any organism.

Development of stable and reproducible transformation and regeneration technologies opened new horizons in banana and plantain breeding. Despite technical difficulties of transforming a monocot species, transformation protocols are now available for most *Musa* cultivars. Several transformation strategies have been published in the last 10 years by different banana biotechnologists (May *et al.*, 1995; Sagi *et al.*, 1995; Becker *et al.*, 2000; Ganapathi *et al.*, 2001; Khanna *et al.*, 2004; Tripathi *et al.*, 2005a).

2.1 Donor Gene, Promoter, Termination Sequence, and Selection Marker

The identification of resistance genes for the diseases facing banana and plantain is critical in order to create transgenic varieties resistant to these diseases. Upon identification of resistance genes, a method of introduction of these transgenes into banana and plantain will be necessary. Genetic transformation could be a useful tool for creating plants with improved characteristics. The status of research on genetic engineering of banana and plantain for disease resistance and future possibilities has also been reviewed (Sagi, 2000; Tripathi, 2003; Tripathi *et al.*, 2005b). Currently, the transgenes used for banana improvement have been exclusively isolated from heterologous sources like other plant species, insects, microbes, and animals (Tripathi, 2003; Tripathi *et al.*, 2004, 2005b).

2.1.1 Isolation and characterization of novel genes: targeted traits

2.1.1.1 Pest resistance

There are several possible approaches for developing transgenic plants with improved weevil and nematode resistance. A variety of genes

are available for genetic engineering for pest resistance (Sharma *et al.*, 2000). Among these are proteinase inhibitors (PIs), *Bacillus thuringiensis* (*Bt*) toxins, plant lectins, vegetative insecticidal proteins (VIPs), and α -amylase inhibitors (AI). PIs contribute to host plant resistance against pests and pathogens (Green and Ryan, 1972). They operate by disrupting protein digestion in the insect mid-gut via inhibition of proteinases. The two major proteinase classes in the digestive systems of phytophagous insects are the serine and cysteine proteinases. Coleopteran insects, including the banana weevil, mainly use cysteine proteinases (Murdock *et al.*, 1987) and recent studies indicate a combination of both serine and cysteine proteinase is useful (Gerald *et al.*, 1997). These inhibitors have already been used for insect control in genetically modified (GM) plants (Leple *et al.*, 1995). Presently, cysteine proteinase activity has been identified in the mid-gut of the banana weevil and *in vitro* studies have shown that cysteine proteinases are strongly inhibited by both a purified recombinant rice (*oryzacystatin-I* (OC-I)) and papaya cystatin (Abe *et al.*, 1987; Kiggundu *et al.*, 2003).

The use of PIs, as nematode antifeedants is an important element of natural plant defense strategies (Ryan, 1990). This approach offers prospects for novel plant resistance against nematodes and reduces use of nematicides. The potential of PIs for transgenic crop protection is enhanced by lack of harmful effects when humans consume them in seeds, such as rice and cowpea. Cysteine PIs (cystatins) are inhibitors of cysteine proteinases and have been isolated from seeds of a wide range of crop plants consumed by man including those of sunflower, cowpea, soybean, maize, and rice (Atkinson *et al.*, 1995). Transgenic expression of PIs provides effective control of both cyst and root-knot nematodes. The cystatins Oc-I and an engineered variant Oc-I Δ D86 were shown to mediate nematode resistance when expressed in tomato hairy root (Urwin *et al.*, 1995), *Arabidopsis* plants (Urwin *et al.*, 1997), rice (Vain *et al.*, 1998a), and pineapple (Urwin *et al.*, 2000). The partial resistance was conferred in a small-scale potato field trial on a susceptible cultivar by expressing cystatins under control of the cauliflower mosaic virus (CaMV) 35S promoter (Urwin *et al.*, 2001). The enhanced transgenic plant resistance to nematodes has

been demonstrated by using dual PI transgenes (Urwin *et al.*, 1998). Since cystatins have been shown to function in rice, which like *Musa* is a monocotyledon, and also have clear efficacy against a wide range of nematode species, their usefulness as transgenes for development of transgenic *Musa* for resistance to nematodes can be evaluated as having a high probability of success. Recently, Cavendish banana (Grand Nain) has been transformed using *Agrobacterium tumefaciens* to express a protein-engineered rice cystatin (Atkinson *et al.*, 2004) and tested in screen house for nematode resistance.

The expression and biological activity of the *Bt* toxins has been investigated in GM plants for insect control. *Bt* gene technology is currently the most widely used system for lepidopteran control in commercial GM crops (Krettiger, 1997). The expression of a selected *Bt* gene for weevil resistance may be a rather long-term strategy since no potential *Bt* gene with high toxic effects against the banana weevil has been identified as yet (Kiggundu *et al.*, 2003). Some *Bt* proteins are also effective against saprophagous nematodes (Borgonie *et al.*, 1996). The Cry5B protein is toxic to wild type *Caenorhabditis elegans*, other *C. elegans* mutants are resistant to Cry5B but susceptible to the Cry6A toxin (Marroquin *et al.*, 2000). The approach using *cry* genes has potential for plant nematode control (Wei *et al.*, 2003).

The other strategies for nematode resistance include the use of natural plant resistance genes (R genes) and lectins genes. Several R genes are targeted against nematodes. The *Hs1pro-1* from a wild species of sugar beet confers resistance to the cyst nematode *Heterodera schachlii* (Cai *et al.*, 1997). Plant lectins confer a protective role against a range of organisms (Sharma *et al.*, 2000). Lectins have been isolated from a wide range of plants including snowdrop, pea, wheat, rice, and soybean. Their carbohydrate binding capability renders them toxic to insects. Some lectins such as the snowdrop lectin (*Galanthus nivalis* agglutinin: GNA) have biological activity against nematodes (Burrows *et al.*, 1998). However, many lectins have toxic effects on insects and mammals, which raise concerns regarding toxicological safety and this, may prove a substantial limitation to the future commercial development of lectins.

AI and chitinase enzymes might also have a future potential for weevil control. AI operate by

inhibiting the enzyme α -amylase, which breaks down starch to glucose in the insect gut (Morton *et al.*, 2000). Transgenic adzuki beans are produced with enhanced resistance to bean bruchids, which are Coleopteran insects like weevils (Ishimoto *et al.*, 1996). Therefore, AI may be of interest for banana weevil control in GM banana. Chitinase enzymes are produced as a result of invasion either by fungal pathogens or insects. Transgenic expression of chitinase has shown improved resistance to Lepidopteran insect pests in tobacco (Ding *et al.*, 1998).

2.1.1.2 Bacterial and fungal resistance

Currently, no source of any banana germplasm exhibiting resistance to the disease has been identified. As an alternative, genetic transformation technology with fungicidal or bactericidal transgenes may offer an alternative solution to these problems.

The most attractive strategy for serious fungal disease like Black Sigatoka control in *Musa* is probably the production of disease resistant plants through the transgenic approach including the expression of genes encoding plant, fungal or bacterial hydrolytic enzymes, genes encoding elicitors of defense response, and antimicrobial peptides (AMPs) (Tripathi, 2005, 2006). AMPs have a broad-spectrum antimicrobial activity against fungi as well as bacteria and most are nontoxic to plant and mammalian cells. Examples of AMPs are magainin from the African clawed frog (Zasloff, 1987; Bevins and Zasloff, 1990), cecropins from the giant silk moth (Boman and Hultmark, 1987), and plant defensins (Broekaert *et al.*, 1995). The cecropin (Alan and Earle, 2002) and its derivatives (D4E1; Rajasekaran *et al.*, 2001) have been found to inhibit the *in vitro* growth of several important bacterial and fungal pathogens. Transgenic tobacco plants expressing cecropins have increased resistance to *Pseudomonas syringae* pv. *tabaci*, the cause of tobacco wildfire (Huang *et al.*, 1997).

Similarly, magainin is effective against the plant pathogenic fungi (Zasloff, 1987; Kristyanne *et al.*, 1997). Li *et al.* (2001) reported enhanced disease resistance in transgenic tobacco expressing Myp30, a magainin analog. Chakrabarti *et al.* (2003) reported successful expression of other

synthetic peptide, MSI-99 and enhanced disease resistance in transgenic tobacco and banana. A synthetic substitution analog of magainin, MSI-99, is employed in this study to impart disease resistance in transgenic tobacco (*Nicotiana tabacum* L.) and banana (*Musa* sp. cv. Rasthali). This peptide inhibited the growth and spore germination of *F. oxysporum* f. sp. *cubense* at 16 lg ml^{-1} . MSI-99 has been subcloned into plant expression vectors pMSI164 and pMSI168, targeting the peptide into the cytoplasm and extracellular spaces, respectively. Tobacco plants transformed with pMSI168 showed enhanced resistance against *Sclerotinia sclerotiorum*, *Alternaria alternata*, and *Botrytis cinerea*. Transgenic banana plants were obtained for both pMSI164 and pMSI168 transformations and showed resistance to *F. oxysporum* f. sp. *cubense* and *Mycosphaerella musicola*. On the basis of the broad-spectrum activity against fungal pathogens, individual or combined expression of cecropin, magainin, and their derivatives in banana may result in increased resistance to several pathogens.

Another source of antimicrobial proteins has been lysozyme, either from bacteriophage, hen eggs, or bovine. The lysozyme attacks the murein layer of bacterial peptidoglycan resulting in cell wall weakening and eventually leading to lysis of both gram-negative and gram-positive bacteria. The lysozyme genes have been used to confer disease resistance against plant pathogenic bacteria in transgenic tobacco (Trudel *et al.*, 1995), potato (Düring *et al.*, 1993), and apple (Ko, 1999).

There are many reports on the application of plant proteins with distinct antimicrobial activities (Broekaert *et al.*, 1997). Thionins are cysteine-rich low molecular weight proteins (about 5 kDa) and have been identified in various organs of a number of plant species. They show antimicrobial activity when tested *in vitro* against various bacteria and fungi (Florack and Stiekema, 1994). The antimicrobial action is based on the ability of thionins to form pores in cell membrane resulting in membrane disruption and cell death. Expression of thionin gene from barley in tobacco confers enhanced resistance to bacterial pathogens (Carmona *et al.*, 1993). Epplé *et al.* (1997) observed that constitutive over expression of thionin in transgenic *Arabidopsis* resulted in enhanced resistance against *F. oxysporum* f. sp.

matthiolae. The expression of thionin, viscotoxin A3, in transgenic *Arabidopsis* showed increased resistance to infection of clubroot pathogen *Plasmodiophora brassicae* (Holtorf *et al.*, 1998). Unfortunately, most thionins can be toxic to animal and plant cells and thus may not be ideal for developing transgenic plants (Reimann-Philipp *et al.*, 1989).

There are a number of known plant defensins, which are known to protect against plant pathogens. The radish defensin Rs-AFP1 and Rs-AFP2, have been shown to inhibit the growth of several pathogenic fungi *in vitro* (Terras *et al.*, 1992). The expression of Rs-AFP2 in transgenic tobacco confers partial resistance to attack by *Alternaria longipes* (Terras *et al.*, 1995). Two homologous peptides, Rs-AFP3 and Rs-AFP4, are also induced in radish leaves upon infection by *A. longipes*, thus further substantiating the role of defensins in plant defense. Two sugar beet leaf defensins, AX1 and AX2, homologs of the radish AFP2, have been isolated after infection with the fungal pathogen *Cercospora beticola* (Kragh *et al.*, 1995). The preliminary results indicate that the expression of these peptides in transgenic corn plants imparts significant resistance to Northern corn leaf blight caused by the fungal pathogen *Exserohilum turcicum*. A defensin from alfalfa seeds alfAFP (alfalfa antifungal peptide) when expressed under the control of 35S promoter in transgenic potato imparted resistance to *Verticillium dahliae*, *Alternaria solani*, and *Fusarium culmorum* but not to *Phytophthora infestans* (Gao *et al.*, 2000). It has shown resistance to fungal diseases in potato in the greenhouse as well as in the field. Kanzaki *et al.* (2002) reported the overexpression of the WTI defensin from wasabi (*Wasabia japonica*) conferring enhanced resistance to blast fungus in transgenic rice.

Several defensins isolated from radish and dahlia have been found toxic to *M. fijiensis* and *F. oxysporum* f. sp. *cubense*, two major fungal pathogens of *Musa* (Cammue *et al.*, 1993). They are nontoxic to human or banana cells. Large number of transgenic lines of *Musa* especially plantains expressing defensins have been developed at KULeuven (Remy, 2000). Many hundreds of transformed lines have been generated and screened under greenhouse conditions in Belgium for disease resistance and the most promising lines

of transgenic bananas and plantains are currently being evaluated in the greenhouse and field in Cuba and Costa Rica.

Plants have their own networks of defense against plant pathogens that include a vast array of proteins and other organic molecules produced prior to infection or during pathogen attack. Pathosystem-specific plant resistance (R) genes have been cloned from several plant species against many different pathogens (Bent, 1996). These include R genes that mediate resistance to bacterial, fungal, viral, and nematode pathogens. Many of these R gene products share structural motifs, which indicate that disease resistance to diverse pathogens may operate through similar pathways. In tomato (*Lycopersicon esculentum*), the R gene *Pto* confers resistance against strains of *P. syringae* pv. *tomato* (Martin *et al.*, 1993; Kim *et al.*, 2002). *Pto*-overexpressing plants show resistance not only to *P. syringae* pv. *tomato* but also to *X. campestris* pv. *vesicatoria* and to the fungal pathogen *Cladosporium fulvum* (Mysore *et al.*, 2003). Similarly, the *Arabidopsis* *RPS4* gene specifies disease resistance to *P. syringae* pv. *tomato* expressing *avrRps4* (Gassmann *et al.*, 1999). The *Bs2* resistance gene of pepper specifically recognizes and confers resistance to strains of *X. campestris* pv. *vesicatoria* (Tai *et al.*, 1999). Transgenic tomato plants expressing the pepper *Bs2* gene suppress the growth of *Xcv*.

The *Xa21* gene isolated from rice has been shown to confer resistance against many isolates of *Xanthomonas oryzae* pv. *oryzae* (Song *et al.*, 1995; Wang *et al.*, 1996). Transgenic plants expressing *Xa21* under the control of the native promoter of the genomic fragment of the *Xa21* gene showed enhanced resistance to bacterial leaf blight caused by most *Xoo* races. The *Xa1* gene also isolated from rice confers resistance to Japanese race 1 of *X. oryzae* pv. *oryzae*, the causal pathogen of bacterial blight (Yoshimura *et al.*, 1998).

Successful transfer of resistance genes to heterologous plant species gives another new option to develop disease resistant plants. R gene-mediated resistance has several attractive features for disease control. When induced in a timely manner, the concerted responses can efficiently halt pathogen growth with minimal collateral damage to the plant. No input is required from the farmer and there are no adverse environmental effects. Unfortunately, R genes are often quickly

defeated by co-evolving pathogens (Pink, 2002). Many R genes recognize only a limited number of pathogen strains and therefore do not provide broad-spectrum resistance. Also efforts to transfer R genes from model species to crops, or between distantly related crops, could be hampered due to restricted taxonomic functionality.

Plants also employ a wide array of defense mechanisms against pathogen attack. Among those, hypersensitive response (HR) is an induced resistance mechanism, characterized by rapid, localized cell death upon their encounter with a microbial pathogen. Several defense genes have been shown to delay the HR induced by bacterial pathogen in nonhost plants through the release of the proteinaceous elicitor. Elicitor-induced resistance is not specific against particular pathogens. Hence, manipulation of such defense genes may be more ideal.

The plant ferredoxin like amphipathic protein (*pflp*, formerly called AP1) and HR-assisting protein (*hrap*), isolated from the sweet pepper, *Capsicum annuum*, are novel plant proteins that can intensify the harpinPSS-mediated HR (Chen *et al.*, 2000). These proteins have dual function: iron depletion antibiotic action and harpin triggered HR enhancing. The transgenes have been shown to delay the HR induced by various pathogens like *Erwinia*, *Pseudomonas*, *Ralstonia*, and *Xanthomonas* sp. in nonhost plants through the release of the proteinaceous elicitor, harpinPss in various crops including dicots like tobacco, potato, tomato, broccoli, orchids, and monocots like rice (Tang *et al.*, 2001; Lu *et al.*, 2003; Huang *et al.*, 2004). Also elicitor-induced resistance is not specific against particular pathogens, so it could be very useful strategy (Wei and Beer, 1996). The research is in progress at IITA for developing bacterial wilt (caused by *X. campestris* pv. *musacearum*) resistant banana varieties using *pflp* or *hrap* genes.

A series of resistance gene analogs have been isolated from banana, using degenerate polymerase chain reaction (PCR) primers targeting highly conserved regions in proven plant resistance genes (e.g., kinase or transmembrane-encoding domains, or leucine-rich repeat sequences). Plant disease resistance genes involved in signal transduction contain domains that are conserved throughout monocotyledons and dicotyledons. Primers have been designed to those domains in the *RPS2* gene of *Arabidopsis* and the *N* gene of tobacco. Using

these primers for PCR, candidate resistance genes have already been cloned from soybean, potato, rice, barley, and *Arabidopsis*. A similar strategy has been applied to clone candidate resistance genes from banana (Wiame *et al.*, 2000). A series of disease resistant genes were isolated from the somaclonal mutant CIEN-BTA-03 (resistant to both *M. fijiensis* and *M. musicola*) and the parent "Williams" that fall into two classes: nucleotide-binding site-leucine-rich repeat-containing kinases, and serine-threonine protein kinases of the *pto* type (Kahl, 2004). All the resistance genes were fully sequenced, and eight of them are also transcribed in the mutant, its parental genotype, "Pisang Mas" and a tetraploid *M. acuminata*. The researchers at Queensland University of Technology (QUT) have isolated the complete gene sequence of R gene candidate (*RGC-2*) from *M. acuminata* ssp. *malaccensis*, a wild diploid banana segregating for resistance to *F. oxysporum* f. sp. *cubense* (FOC) race 4. The development of *Fusarium* wilt resistant transgenic banana using this gene is in progress (Dale *et al.*, 2004).

2.1.1.3 Virus resistance

The most promising transgenic strategies for the ssDNA viruses like banana bunchy top virus (BBTV) is expressing a defective gene that encodes an essential virus life cycle activity, for instance, the replication of the virus is encoded in the replication gene or genes (*Rep*). Resultant Rep protein may retain the ability to bind to its target viral DNA but lack the functions of the *Rep* (Brunetti *et al.*, 2001). The defective Rep protein binds to the invading viral DNA and is thought to outcompete the native viral Rep protein, thus reducing or eliminating virus DNA replication. Lucioli *et al.* (2003) expressed the first 630 nucleotides of the *Rep* gene of tomato yellow leaf curl Sardinia virus (Acronymn) to generate resistance. The duration of the resistance was related to the ability of the invading virus to switch off transgene expression through post-transcriptional gene silencing (PTGS). Many researchers are trying to develop transgenic plants of *Musa* resistant to BBTV targeting the PTGS mechanism using mutated or antisense *Rep* genes.

Unfortunately, there appear to be no strategies that have been developed that generate high-level resistance to the plant dsDNA or pararetroviruses,

including the badnaviruses. Researchers at IITA, Nigeria in collaboration with the John Innes Centre (JIC), UK, are attempting to generate transgenic resistance to banana streak virus (BSV) based upon PTGS. The construct used for transformation is pC-BB with a BSV sequence from the viral reverse transcriptase-RNaseH domain under the regulation of CaMV 35S promoter. This approach involves the specific silencing of a viral gene or genes known to be involved with replication or pathogenesis.

2.1.1.4 Edible vaccine

Researchers are working to develop a banana that is an “edible vaccine” to fend off hepatitis, one of the world’s most widespread and devastating diseases. Charles Arntzen’s group at Boyce Thompson Institute for Plant Research, USA had successfully developed tobacco plants producing a vaccine against hepatitis B. It was found that the vaccine produced in plants is similar in form and function to that from human serum or recombinant yeast and provoked a strong immune response when injected into mice, while B and T-cell epitopes were preserved. Successful expression of antigens in plants was also achieved for Rabies virus G-protein in tomato (McGarvey *et al.*, 1995), Norwalk virus capsid protein in tobacco and potato (Mason *et al.*, 1996), Hepatitis B virus surface antigen in tobacco and potato (Thanavala *et al.*, 1995), *Escherichia coli* heat-labile enterotoxin B subunit (LT-B) in tobacco and potato (Hirst and Holmgren, 1987), Cholera toxin B subunit (CT-B) in potato (Arakawa, 1997). Foods under study include potatoes, bananas, lettuce, rice, wheat, soybean, corn, and legumes. Banana is a good candidate for edible vaccines since they were eaten raw, appealing to children, inexpensive to produce, native to many developing countries (Hassler, 1995). But the only limitation is the time from transformation to evaluation of fruit is 2 years or more.

Embryogenic cells of banana cv. Rasthali (AAB) have been transformed with the “s” gene of hepatitis B surface antigen (HBsAg, Kumar *et al.*, 2005). Higher monoclonal antibody binding of 67.87% of the antigen was observed when it was expressed with a C-terminal ER retention signal. HBsAg obtained from transgenic banana plants is

similar to human serum derived one in buoyant density properties. The transgenic plants were grown up to maturity in the green house and the expression of HBsAg in the fruits was confirmed by RT-PCR. These transgenic plants were multiplied under *in vitro* using floral apex cultures. Attempts were also made to enhance the expression of HBsAg in the leaves of transgenic banana plants by wounding and/or treatment with plant growth regulators. This is the only report on the expression of HBsAg in transgenic banana fruits.

2.1.2 Promoters

Plant genetic transformation is a potential tool in different areas such as manipulation and understanding of biochemical processes, knowledge of genome regulation, and integration of genes, which cannot be manipulated by classical breeding. In order to apply genetic engineering to both crop improvement and basic research, the availability of a variety of promoters that confer constitutive, i.e., expression in all cell types, tissue-specific, or developmental-specific transgene expression is required. Often a strong constitutive promoter is required to ensure sufficient expression of the transgene throughout the plant. Several such promoters have been isolated that direct strong constitutive expression in monocot plants. These include the maize ubiquitin promoter, the rice actin1 promoter, various enhanced CaMV 35S, and the synthetic pEmu promoter (Kay *et al.*, 1987; McElroy *et al.*, 1990; Christensen and Quail, 1996; Mitsuhashi *et al.*, 1996). However, the promoter activity can vary in different plant species and not all of these promoters can be used for high-level expression in all monocot species. Variation in transgene expression levels between different species and promoters may be due to different abundance of transcription factors, recognition of promoter sequences or intron splicing sites, or other factors (Wilmink *et al.*, 1995).

Most commonly used constitutive promoter is the CaMV 35S, a promoter active in most stages of development and in most plant tissues. However, it has been widely used for high-level constitutive expression in dicots, but confers lower levels of expression in monocots. Promoters isolated from monocots generally show higher activity in monocots, and adding an intron between the

promoter and the reporter gene can increase transcription levels (Rathus *et al.*, 1993). The rice actin promoter *Act1* (McElroy *et al.*, 1990) and the maize ubiquitin promoter *Ubi* (Christensen and Quail, 1996) achieved far better expression than the CaMV 35S in most monocots tested.

Effective applications of genetic engineering, however, are frequently likely to be dependent on the use of promoters specific to particular tissues or developmental events. It is desirable, for example, for nematode resistance to be expressed only after nematodes begin to feed and in the roots requiring the splicing to the resistance gene of a combination of suitable promoters. The approach for finding such promoters is to identify any gene expression with the required tissue or developmental specificity, and then to isolate the regulatory elements and test for specificity.

Currently, only a few promoters are widely used for plant transformation. Promoters can have different expression patterns even in closely related species; therefore information gathered from other transformation experiments may not be completely representative of the expression pattern of that specific promoter in banana. Therefore, the different promoters will have to be tested in banana in order to identify promoters that will be suitable for use in different transformation projects.

The production of transgenic bananas harboring genes encoding an improved genotype requires strong promoters for both constitutive and regulated high-level expression of the transgenes. Generally speaking, not enough promoters are available, though several groups are actively working to isolate useful promoter sequences, or at least fragments with promoter activity. Commonly used promoters in banana transformation are rice actin, CaMV 35S, and maize ubiquitin (Table 1). A number of monocot active promoters have been isolated from viruses infecting both dicot and monocot plants and are potential promoters for banana transformation. A promoter was isolated from sugarcane bacilliform badnavirus and showed expression in constitutive manner in banana and tobacco (Schenk *et al.*, 1999). This promoter represents a useful tool for the high-level expression of foreign genes in both monocot and dicot transgenic plants that could be used similarly to the CaMV 35S or maize ubiquitin promoter. Promoters from BSV were proved to drive high expression of *gusA* (β -glucuronidase) reporter

genes in transgenic monocot (banana, barley, maize, millet, sorghum) and dicot plants (canola, sunflower, tobacco), and also in *Pinus radiata* and *Nephrolepis cordifolia* (Schenk *et al.*, 2001). In greenhouse experiments with banana transgenics, the BSV promoter was found to be superior to the widely used maize ubiquitin and CaMV 35S promoters. Promoter regions of BBTv have been characterized. DNA segments incorporating the intergenic regions of BBTv DNA components S1 and S2 were isolated and fused to the *gusA* reporter gene to assess promoter activity in tobacco and banana (Hermann *et al.*, 2001). BBTv S1 and S2 promoters supported vascular tissue-associated reporter gene expression, and can certainly be exploited as tissue-specific promoters.

Up to date, the only constitutive heterologous promoters (the maize ubiquitin 1 and the rice actin 1 promoters) or viral promoters (derived from the BSV and BBTv) have been used for the production of transgenic banana plants (Table 1). For a number of future applications, transgenes will have to be expressed differentially or under specific abiotic (e.g., salt, wounding) and biotic stress conditions, which requires the use of a set of specific promoters to drive regulated gene expression. However, relatively few promoters are currently available for a specific or fine regulation of gene expression. It is expected that for these purposes homologous promoters will be more functional than heterologous ones, which should also raise less biosafety concerns. Many promoters have been identified directly from the banana genome by using a transfer DNA (T-DNA) tagging method with a promoterless codon-optimized luciferase (*luc*) gene (Remy *et al.*, 2005). A series of promoters has also been isolated from genes induced after challenge with a fungus. Isolation of promoters for banana transgenics, using modern technique like TAIL-PCR or other walking techniques is routine these days (Terauchi and Kahl, 2000). Commonly used terminators for banana transformation are the nopaline synthesis (NOS) and CaMV 35S.

2.1.3 Selection marker and reporter genes

Plant transformation is based on the delivery, integration, and expression of defined genes into plant cells, which can be grown to generate

transformed plants. Efficiency of stable gene transfer is not high even in the most successful transfer systems and only a fraction of the cells exposed integrate the DNA construct into their genomes. Moreover, a successful gene transfer does not guarantee expression, even by using signals for the regulation of transgene expression. Therefore, systems to select the transformed cells, tissues, or organisms from the nontransformed ones are

indispensable to regenerate the truly genetically transformed organisms.

The use of genes encoding for antibiotic or herbicide resistance has assisted the selection of transformants in the background of untransformed ones. The neomycin phosphotransferase II (*nptII*) gene that confers resistance to aminoglycoside antibiotics such as kanamycin and its analogs paromomycin and geneticin, and hygromycin

phosphotransferase (*hpt*) gene, which confers resistance to hygromycin have been successfully used as selectable marker in transformation of a variety of crop plants, including dicots and monocots. Similarly the *bar* (bialaphos resistance) and *pat* (phosphinothricin acetyltransferase) genes that confer resistance to the herbicide BASTA[®] and phosphinothricin respectively, have also provided an efficient selection of transgenics in a number of crops.

Herbicide or antibiotic assays, which kill or suppress nontransformed cells, while allowing proliferation of transformed tissues, are attractive, but sensitivity of tissues to the selecting agent is critical. A high incidence of untransformed “escapes” has been demonstrated in some studies; therefore, better selection markers are needed.

The *ipt* gene encodes the enzyme isopentenyl transferase and is located on Ti-plasmids of *A. tumefaciens*. This enzyme catalyzes the condensation of isopentenyl pyrophosphate with AMP to produce isopentenyl AMP, a precursor of several cytokinins (Akiyoshi *et al.*, 1984). Cytokinins stimulate organogenesis in many cultured plant tissues and are widely used to regenerate transgenic plants from cultured cells after transformation. When a chimeric *ipt* gene under the control of the CaMV 35S promoter was introduced into cells of potato, cucumber, and several *Nicotiana* species, transgenic cells proliferated and adventitious shoots differentiated in hormone-free medium (Smigocki and Owens, 1988). These transgenic plants exhibited loss of apical dominance. Therefore, it is easy to detect visually transgenic plants that carry a functional *ipt* gene. Chimeric *ipt* genes are not commonly used as selectable markers because the resulting transgenic plants lose apical dominance and are unable to root due to overproduction of cytokinins. Ebinuma *et al.* (1997) developed the multi-auto-transformation (MAT) vector system, in which the selectable marker is composed of a chimeric *ipt* gene inserted into the maize transposable element *Ac* to overcome some of the difficulties of the current transformation methods. It has been demonstrated that marker-free transgenic plants can be visually selected by using the chimeric *ipt* gene as a marker gene in tobacco plants and hybrid aspen. This method could be particularly valuable

for fruit like banana and forest trees, for which long generation times are a more significant barrier to breeding and genetic analysis.

There are several ways of determining where and when a particular gene is expressed in a plant. Most commonly used approach is the use of a reporter gene. A reporter gene produces a protein that is easily detectable in transformed organisms. Often, the protein possesses an enzymatic activity that can turn a colorless substrate into a colored product. Thus, one can see the location and amount of gene expression in a transformed organism by looking at the location and intensity of the colored product. The β -galactosidase (*lacZ*) and β -glucuronidase (*gusA*) genes are two examples of these reporter genes. When the reporter gene is fused to the promoter of the gene of interest, the reporter gene will be expressed only at the times and locations where the gene is expressed. This provides a method to detect a very limited expression of a gene, such as in small patches of cells (like root tips or pollen) or at certain times (such as after a certain stress or hormone treatment).

The green fluorescent protein (*gfp*) gene is an ideal selectable marker and reporter for gene expression analysis and plant transformation. The *gfp* gene, isolated from jellyfish, *Aequorea victoria*, encodes a small, barrel-shaped protein surrounding a fluorescent chromophore, which immediately emits green fluorescent light in the blue to ultraviolet range. Visual detection is possible at any time in living cells without their destruction and without the addition of any cofactor or external substrate. In addition, *gfp* gene product does not adversely affect cell growth, regeneration, and fertility of transformed plants. The availability of mutant forms of *gfp* differing in solubilities and emission spectra make it possible to simultaneously monitor multiple transformation events within an individual transformant (Stuber *et al.*, 1998). Green fluorescent protein (GFP) has been of great use when the organogenesis or conversion segments of transformation are inefficient under antibiotic and herbicide selection. In the beginning, GFP was used in conjunction with antibiotics and herbicides and has been shown to decrease the number of escapes for a number of tree species (Tian *et al.*, 1997). Recently, *gfp* has been used as a sole visual selectable marker in genetic transformation

of monocots like barley (Ahlandsberg *et al.*, 1999), oat (Kaeppler *et al.*, 2000), and rice (Vain *et al.*, 1998b). GFP selection system seems to be promising for tissue culture/transformation systems that are inefficient, for recalcitrant genotypes, and for plant species for which no system exists. Most commonly used reporter genes in banana transformation are *gusA* and *gfp* under the regulation of constitutive promoters Act1, CaMV 35S, and Ubi (Table 1).

2.2 Transformation Methods Employed

Genetic transformation offers an attractive means for introduction of agronomically important genes into banana cultivars. Some success in genetic engineering of bananas and plantains has been achieved recently to enable the transfer of foreign genes into plant cells. Gene insertion in plants can be achieved by direct gene transfer through particle bombardment or through biological vectors like a disarmed Ti (tumor inducing)-plasmid of *A. tumefaciens*. Genetic transformation using microprojectile bombardment of embryogenic cell suspension (ECS) is now routine (Sagi *et al.*, 1995; Becker *et al.*, 2000). An efficient method for direct gene transfer via particle bombardment of ECS has been reported in cooking banana cultivar Bluggoe and plantain Three Hand Plant (Sagi *et al.*, 1995). While Becker *et al.* (2000) reported the genetic transformation of Cavendish banana cv. Grand Nain.

Agrobacterium-mediated transformation offers several advantages over direct gene transfer methodologies (particle bombardment, electroporation, etc.), such as the possibility to transfer only one or few copies of DNA fragments carrying the genes of interest at higher efficiencies with lower cost and the transfer of very large DNA fragments with minimal rearrangement (Shibata and Liu, 2000). Therefore, transformation of plants by *Agrobacterium*-mediated DNA transfer is currently the most commonly used phenomenon in accomplishing plant gene transfer (Lindsey, 1992). For quite some time banana was generally regarded as recalcitrant for *Agrobacterium*-mediated transformation. However, Hernandez *et al.* (1999) has reported that *A. tumefaciens* is compatible with banana indicating the potential

for genetic transformation. The recovery of transgenic plants of banana obtained by means of *Agrobacterium*-mediated transformation has been reported. The protocol has been developed for *Agrobacterium*-mediated transformation of ECS of the banana cultivars Rasthali, Cavendish, and Lady finger (Ganapathi *et al.*, 2001; Khanna *et al.*, 2004). Ganapathi *et al.* (2001) reported *Agrobacterium*-mediated transformation of shoot apex derived ECS of cultivar Rasthali (AAB) recording production of up to 40 plants per 0.5 ml packed cell volume in this cultivar. Banana functional genomics and plant improvement initiatives demand higher transformation frequencies and a standard protocol that can be used to transform all banana genomic groups including the high demand cultivars of AAA group, e.g., Cavendish. Khanna *et al.* (2004) described centrifugation-assisted *Agrobacterium*-mediated transformation protocol developed using banana cultivars from two economically important genomic groups (AAA and AAB) of cultivated *Musa*. This protocol resulted in 25–65 plants per 50 mg of settled cell volume of embryogenic suspension cells, depending upon the *Agrobacterium* strain used, and gave rise to hundreds of morphologically normal, transgenic plants in two banana cultivars from the two genomic groups.

At present most of the transformation protocols use cell suspension, however establishing cell suspension is a lengthy process and cultivar dependent. The protocol has also been established using shoot tips from various cultivars of *Musa* (May *et al.*, 1995; Tripathi *et al.*, 2005a). This technique is applicable to a wide range of *Musa* cultivars irrespective of ploidy or genotype (Tripathi *et al.*, 2003, 2005a). This process does not incorporate steps using disorganized cell cultures but uses micropropagation, which has the important advantage that it allows regeneration of homogeneous populations of plants in a short period of time. This procedure offers several potential advantages over the use of ECS as it allows for rapid transformation of *Musa* species and meristematic tissues have potential to regenerate plants from many different cultivars, unlike somatic embryogenesis, which is restricted to only a few cultivars. The transformation of meristematic cells may result in chimeric plants when only one or a few cells receive T-DNA. To

obtain uniformly transformed plants, two steps of selection and regeneration were performed to avoid regeneration of any nontransformed cells. The transformation of East African Highland bananas using meristematic tissues has also been established (Tripathi *et al.*, 2008).

Development of a highly efficient *Agrobacterium*-mediated transformation protocol for a recalcitrant species like banana requires the identification and optimization of the factors affecting T-DNA delivery and subsequent plant regeneration. Preinduction of *Agrobacterium* with acetosyringone (Khanna *et al.*, 2004; Tripathi *et al.*, 2005a) and use of surfactants like Pluronic F68 (Cheng *et al.*, 1997) have been reported to have a positive effect on *Agrobacterium*-mediated transformation. Hernandez *et al.* (1999) reported chemotactic movement and attachment of *A. tumefaciens* to wounded tissues of banana cultivars belonging to different genomic groups. Microprojectile bombardment is reported to be an effective method of wounding tissues to promote *Agrobacterium*-mediated transformation (Bidney *et al.*, 1992). We observed a significant increase in transformation efficiency measured as transient expression of reporter gene, in explants microwounded by microprojectile bombardment with naked gold particle prior to co-cultivation with *A. tumefaciens*. This improvement in transformation efficiency can be attributed to the initiation of active cell division upon wounding (Sangwan *et al.*, 1992), the improved binding of *Agrobacterium* to the newly synthesized cell wall at the wound sites (Binns, 1991), and the production of *vir*-inducing compounds by the metabolically active cells (Stachel *et al.*, 1985).

Differences are known to exist between infection efficiencies of different Ti plasmid vectors and virulence of *Agrobacterium* strains. To date, the published reports of banana transformation via *Agrobacterium* described only three different strains, i.e., LBA4404, disarmed C58, and EHA101; and their derivatives (EHA105 from EHA101, AGL0 and AGL1 from EHA101) as mentioned in Table 1. *Agrobacterium* supervirulent strains EHA105 and AGL1 derivative of EHA101 were found to be better in comparison to the normal strain LBA4404 (Khanna *et al.*, 2004; Tripathi *et al.*, 2005a). Antibiotics such as cefotaxime, carbenicillin, and timentin have been used regularly in *Agrobacterium*-mediated

transformation of banana following coculture to suppress or eliminate *Agrobacterium*.

2.3 Selection of Transformed Tissue

A critical factor in transformation is the selection of transformed cells, since for each transformation event; the introduced gene(s) will be incorporated into only a fraction of the cells subjected to transformation. This selection is performed with the help of a selectable marker gene, which confers resistance to chemical agents, such as antibiotics, herbicides, which are otherwise toxic to plant cells. An effective selection process is needed to increase the efficiency of transformant recovery. For banana transformation, antibiotic resistance genes are widely used to enable this selection.

The most widely used selectable markers in monocot transformation are the genes encoding *hpt*, phosphinothricin acetyltransferase (*pat* or *bar*), and *nptII*. Use of these marker genes under the control of constitutive promoters such as the 35S promoter from CaMV, or the ubiquitin promoter from maize, works as efficiently for selection of *Agrobacterium*-transformed cells as for biolistic-mediated transformation. For banana, the *nptII* gene under the control of the NOS or CaMV 35S promoter has been used to successfully select stable transformants with kanamycin, similar to many standard dicot transformation protocols (Table 1). Kanamycin and hygromycin proved to be equally effective as selection agents (Khanna *et al.*, 2004).

Matsumoto *et al.* (2002) reported the use of *ahas* (acetohydroxyacid synthase) gene as a new selectable marker for banana transformation. Acetohydroxy acid synthase (AHAS) is the target enzyme for AHAS-inhibiting herbicides such as imidazolinones and sulfonylureas. Embryogenic cells of “Maçã” banana (*Musa* sp. AAB group, Silk) were bombarded with a plasmid vector containing the *ahas* gene, under control of the *ahas* promoter from *Arabidopsis*. The bombarded cells were regenerated on selected medium containing Imazapyr herbicide.

Dominant genes encoding either antibiotic or herbicide resistance are widely used as selectable markers in plant transformation (Yoder and Goldsbrough, 1994). The antibiotics and herbicides that select rare transgenic cells from non-

transgenic cells generally have negative effects on proliferation and differentiation. These agents may retard differentiation of adventitious shoots during the transformation process. Some plant species are insensitive to or tolerant of the selective agents and, therefore, it is difficult to separate the transformed and untransformed cells or tissues. Therefore, it is difficult to find appropriate selectable markers and to establish optimal conditions for transformation of such difficult species. Selectable marker genes remain in transgenic plants, and their gene products need to be assessed for safety and environmental impact (Flavell *et al.*, 1992).

It is difficult to introduce a second gene of interest into a transgenic plant that already contains a resistance gene as a selectable marker. There are a large number of desirable traits and genes worth incorporating into plants, but only a limited number of selectable marker genes are available for practical use. The problem becomes even more difficult if one wants to introduce a number of genes, and it is impossible to introduce them simultaneously (Goldsbrough, 1992; Yoder and Goldsbrough, 1994). It is desirable, therefore, to develop a system for the removal of selectable marker genes to produce environmentally safe transgenic plants and pyramid a number of transgenes by repeated transformation.

The positive selectable marker phosphomannose isomerase was first used for *Agrobacterium*-mediated transformation of dicot plants, i.e., sugarbeet (Joersbo *et al.*, 1998), and it has now been shown to be effective in transformation of monocots, such as rice and maize as well (Negrotto *et al.*, 2000; Lucca *et al.*, 2001). This can be a potential selection marker for banana transformation also.

2.4 Regeneration of Whole Plant

The introduction of transgene into a desired plant species for the development of stable transgenic plants requires an efficient regeneration system amenable to genetic transformation and stability of transgenes under field conditions. *In vitro* regeneration is the technique of growing plant cells, tissues, or organs isolated from a source plant. It has been found that plants can reproduce whole plants from fragments of plant material when given a nutrient media capable of supporting growth and

appropriate hormone control under laboratory condition. With the advent of gene insertion, plant cells with gene material inserted can be regenerated using *in vitro* culture to produce a whole plant. Plant regeneration of banana has been reported from various explant sources and from a variety of cultivars. Depending on different explants in combinations with various growth regulators, regeneration occurs via micropropagation or ECS.

2.4.1 Micropropagation

Micropropagation is the process by which explants having the pre-existing meristems lead to the development of multiple shoots. This is by far the most routinely applied technique used in plant tissue culture. Multiplication rate is several orders of magnitude larger than in the field. Indeed, while *in situ* a banana plant will produce about 10 shoots after 1 year, a shoot meristem *in vitro* can produce about 125–144 shoots within 8 weeks. Through repeated subculturing of proliferating shoots, an open-ended system can be maintained (Tripathi *et al.*, 2003). Propagation from existing meristems yields plants that are genetically identical to the donor plants. The shoot tip culture technique offers several additional advantages like clean planting material and *in vitro* preservation and exchange of banana germplasm.

The micropropagation technique for cultivated *Musa* is now well established (Cronauer and Krikorian, 1984; Banerjee and De Langhe, 1985). Shoot tip culture is easy and applicable to a wide range of *Musa* genotypes. An efficient regeneration protocol, which seems to be independent of ploidy level and genomic background, was developed for *Musa* species using apical meristems (Tripathi *et al.*, 2003). The selected species represent major groups of *Musa* including fertile diploid bananas (AA and BB genomes), the sterile triploid plantains (AAB), Cavendish bananas (AAA), and tetraploid hybrids (AAAA and AAAB).

Micropropagation has played a key role in banana improvement programs worldwide. Planting material derived from micropropagation performs equal to or superior to conventional material. Micropropagated plants establish faster, grow more vigorously, are taller, have a shorter and more uniform production cycle, and yield higher than conventional propagules.

2.4.2 Embryogenic cell suspension

Somatic embryogenesis is a process where a group of somatic cells/tissues leads to the formation of somatic embryos that resemble the zygotic embryos of intact seeds and can grow into seedlings on suitable medium. ECS appear, as is the case with most monocotyledons, to be the material of choice for nonconventional *Musa* breeding.

Recently, much progress has been made in the establishment of embryogenic cell culture from banana explant sources and from a variety of cultivars. Novak *et al.* (1989) established embryogenic suspensions from somatic tissues such as leaf sheaths and corm sections of Grand Nain cultivar. For the cultivar Bluggoe, Dheda *et al.* (1991) cultured their sections from highly proliferated shoot tip cultures to produce ECS cultures. Embryogenic suspensions have also been established from immature zygotic embryos (Escalant and Teisson, 1989; Marroquin *et al.*, 1993). However, male flowers are the most responsive starting material for initiating embryogenic cultures of cv. Grand Nain (Escalant *et al.*, 1994; Cote *et al.*, 1996; Navarro *et al.*, 1997; Sagi *et al.*, 1998) and cultivar Rasthali (Ganapathi *et al.*, 2001). These suspension cultures can be regenerated into plantlets through somatic embryogenesis at high frequencies and grown in the field (Novak *et al.*, 1989; Dheda *et al.*, 1991).

Suspension culture promises a tool for faster multiplication rate than shoot tip cultures. Also, it allows for a quick response to demands and offers possibilities for automated multiplication. ECS cultures have successfully been used for cryopreservation (Panis *et al.*, 1996). The conservation of banana germplasm under cryopreserved conditions is an attractive alternative to the conservation of actively growing meristem tips. Plant regeneration from cell suspension cultures was investigated for its potential in mass propagation and as a tool in transformation using recombinant DNA technology. However, most of the procedures of developing ECS are still laborious, time consuming, and genotype dependent.

2.5 Testing

The proof of stable genetic transformation is the determination of integration of the foreign

DNA into the chromosome of the recipient plants. In early developing stages of a transformation system qualitative expression assays of the β -glucoronidase (GUS) or the GFP, encoded by the *gusA* and *gfp* reporter-genes, respectively, have been successfully used to monitor transgene delivery into banana tissues. The resulting banana transgenic plants are carefully evaluated for transgene integration, expression, and stability of transgene expression. A molecular and genetical screening is necessary to identify individual transformants with desired characteristics, such as single inserts, desired expression level, and single locus integration, etc.

Two molecular techniques, PCR and Southern blot analysis, are widely used to evaluate banana transgenic plants for transgene integration and integration patterns. Further, the expression of a transgene is evaluated at the RNA, protein, and bioassay levels. The presence of transgenic RNA demonstrates that the transgene is actively transcribed. Translation of transgene into the encoded protein can be demonstrated with Western blot or enzyme-linked immunosorbent assay (ELISA). Several bioassays have been developed for transgene expression for disease resistance in banana for example, leaf bioassay for testing gene expression for resistance to banana *Xanthomonas* wilt.

The transgenic plants are further tested for the desired agronomic performance in confined field trail. Rahan Meristem Ltd, recently conducted field trials of transgenic bananas growing plants in an area heavily infested with nematodes and the plants showed complete resistance (FreshPlaza, 2006). The nematodes could not reproduce on the transgenic banana plants developed by use of a special technology called RNA interference (RNAi).

During the last 10 years, after the public sector had developed the transformation technology, large-scale commercial producers of banana invested considerable additional resources in the research for transgenic solutions, especially to the problems of black Sigatoka disease and nematodes. Considerable progress has been made but failed to reach the stage of deploying commercially useful varieties. This effort has left a legacy of relevant technologies but the use of many of them, at least beyond the stage of experimentation, is severely limited by intellectual

property constraints, many of which remain unsolved in the absence of a clear policy on the use of transgenic banana by the private sector.

In the absence of commercial transgenic banana varieties, there has not been the level of private sector investment in biosafety testing. However, with the entry of countries such as Brazil and South Africa, which already have substantial areas of transgenic crops, into the field of genetic modification of *Musa*, more rapid progress is now expected. Meanwhile a number of developing countries are putting in place the necessary legal framework for testing and dissemination of GM crops, either specifically in order to facilitate the development of transgenic bananas, as in the case of Uganda, or in order to benefit from a range of transgenic crops that may in due course include banana and plantain.

2.6 Regulatory Measures Adopted

Regulations governing genetically modified organisms (GMOs) can potentially act at a number of key stages. Development of GM variety is a long process. Development of GM banana is in its initial stages in the laboratory, where the GMOs are produced and presence of the transgene is confirmed etc., and proceeds to field testing of the organisms produced to ensure they have the desired characteristics. Regulations at this stage may cover the conditions under which laboratory experiments take place; exchange of GM material between laboratories and conditions for testing GMOs in greenhouses, other contained facilities, or in the field. After the Research and Development stage, there may be interest in bringing the GM product to the market. Regulations here may cover assessment of the potential human health and environmental risks, to be carried out prior to eventual approval. If approval is granted, the next stage is the commercial release of the GM banana. Till date, there is no commercial release of transgenic banana and plantain.

Banana and plantain are important crops in most tropical and subtropical regions of the world. Many developing countries are beginning to develop regulations related to genetically engineered products (James, 1998). Furthermore, operational field-testing regulations have been implemented

in, for example, Argentina, Brazil, Mexico, Chile, Costa Rica, Cuba, India, Philippines, and Thailand. But still the majority of developing countries currently do not have a regulatory system for GMOs in place. Development of a regulatory framework may be a costly, time-consuming process involving extensive consultation and effort.

Many countries in sub-Saharan Africa are now establishing national biosafety committees and biosafety regulations for testing and dissemination of GM crops, specifically in order to facilitate the development of transgenic bananas in many countries like Uganda, Egypt. There are also initiatives to harmonize biosafety regulations at the regional level. The Food and Agricultural Organization (UN) is now focusing its biotechnology programme toward providing technical advice and capacity building regarding biosafety to its member governments. The Program for Biosafety Systems (PBS) is another important initiative that has been established to assist national governments in studying the policies and procedures necessary to evaluate and manage potential harmful effects of modern biotechnology on the environment and human health. The program's unique approach addresses biosafety as part of a sustainable development strategy, anchored by agriculture-led economic growth, trade, and environment objectives. Many countries have signed the Cartagena Protocol on Biosafety to the UN Convention on Biological Diversity agreed to put in place measures to ensure the safe handling of GMOs within countries and their transfer across national boundaries.

A number of existing international agreements have direct relevance to GMOs and they can be of assistance to developing countries in establishing appropriate regulatory structures that deal with potential concerns while, at the same time, promoting harmonization of national regulations at the international level.

3. FUTURE ROAD MAP

Bananas and plantains are seriously threatened by pests and numerous viral, bacterial, and fungal diseases. Thus, resistance to biotic stresses is an important part of regional or national efforts. Since all the cultivated varieties of banana are sterile

and, therefore, do not set seed, traditional breeding is more difficult than genetic transformation using molecular techniques. Although attempts to produce transgenic bananas and plantains are still proceeding too slowly, public acceptance of these novel plants and their products should already be prepared for through sound information and risk assessment, although the chances of transfer of transgenes from transgenic field material to wild species (the major public concern) are expected to be negligible in view of the sterility of many cultivars. The scope for further improvement of *Musa* species is large; along with other methods of crop improvements transgenic technologies should provide fast and effective methods of *Musa* improvement.

The number of transgenic bananas is continuously increasing. Transformation protocols, including tissue culture techniques, suitable transformation constructs with modified promoters driving one or more transgene(s), appropriate transformation techniques such as particle bombardment and *Agrobacterium*-mediated gene transfer, the detection of the transgenes and characterization of their insertion sites (copy number), are well developed. Transgenes have been used exclusively from heterologous sources rather than specifically from bananas.

3.1 Expected Products

The major research institutes/organizations and universities are concentrating on the development of two broad types of proprietary traits: (a) input traits such as pest or disease resistance and (b) output traits that improve the nutritional contents of foods or exhibit unique properties for very specific end uses or markets. Such input and output traits will be incorporated into existing elite varieties to provide material with further added value, which may offer to the farmers at lower costs or higher yield, and increased value of the end product. Initially, it is likely that transgenic banana varieties brought to the market will focus on diseases (bacterial and fungal) and pest (nematode) resistance as the technologies are in advanced stage in many laboratories. However, the long-term commercial potential of plant biotechnology is considered to be in the development of value-added output traits that will

address a wide range of specific needs or market niches.

Genetic modification of banana has also been considered as a means toward increasing the value of this crop to health and nutrition in developing countries. As a crop that is widely consumed as a weaning food by children and as a starchy staple by all sectors of the community in some countries, banana has been advocated as a carrier for vaccines and as a source of carotenoids that can counteract debilitating vitamin A deficiency. However, although much of the necessary technology is now available, these applications have yet to advance to the stage of practical evaluation.

Nutritionally enhanced crops could make a significant contribution to the reduction of micronutrient malnutrition in developing countries. Biofortification (the development of nutritionally enhanced foods) can be advanced through the application of several biotechnologies in combination. Genomic analysis and genetic linkage mapping are needed to identify the genes responsible for natural variation in nutrient levels of common foods. These genes can then be transferred into popular cultivars through breeding or, if sufficient natural variation does not occur within a single species, through genetic engineering. Vitamin and mineral deficiencies, which contribute to the deaths of millions of children each year, can be easily prevented by adding just a few key nutrients to staple food.

Transgenic plants that produce medicinal compounds such as subunit oral vaccines have already been developed, but experts concede that application of this technology is at least a decade away. There are several technical problems, which need to be addressed before plant edible vaccines become a reality in practice. Most inserted genes are expressed in very low levels in plants, which need to be enhanced. Arntzen *et al.* (2005) recently reported that a synthetic cholera vaccine gene that was more "plant" like in its sequence is four times more productive than the original gene. The stability of vaccine proteins when transgenic fruits or leaves are stored at ambient conditions is another concern. There are also concerns about oral tolerance and the dosage of oral vaccine. Only further collaborative research between plant and medical scientists may resolve these and other issues. In the near term,

the edible-vaccine technology might be better targeted at animals. In fact, such an approach may benefit agriculture as billions of dollars are spent presently on vaccinating farm animals and poultry. Transgenic plants supplying feedstock containing edible vaccines may represent the first commercial application of this intriguing technology.

The next future product can be banana varieties with longer shelf life. Banana is the most widely consumed fruit worldwide. Fruits are picked before they are allowed to ripen. They are then transported to their final destination under controlled atmospheric conditions where they are gassed with a plant hormone, ethylene, to induce ripening. Once ripening has been artificially triggered, the fruit has to be eaten or sold immediately before they spoil. First round of banana field trials by Senesco Technologies, Inc. and Rahan Meristem show that using Senesco's delayed ripening technology significantly extends the shelf life of banana. Senesco claims that banana fruit lasted twice as long as the control (nonenhanced) fruit (Crop Biotech Update, 2003). The Senesco bananas ripened normally, but the onset of spoilage and blackening that follows ripening was significantly delayed. The banana field trials indicate that the delayed ripening technology slows the process of cell death once ripening has occurred, without affecting normal growth of the plant and its fruit. This ensures that bananas are the same size, shape, weight, and color as non-enhanced bananas, with the same taste and nutritional characteristics.

Global Agricultural production has been seriously threatened with the continuing deterioration of arable land, scarcity of water, and increasing environmental stress. Over the recent decades, rainfall has seemingly become less reliable, which is putting pressure on the food security and livelihood status of smallholder farmers in sub-Saharan Africa. Drought does not only affect typical dry land but increasingly affects the more semi-humid areas where crops such as cassava and banana dominate. For example, East African highland bananas would need an annual precipitation of at least 1200 mm, but in some recent years annual precipitation in many banana growing areas dropped to below 800 mm rainfall, resulting in yield losses of more than 50% (P. Van Asten, IITA, personal communication). Conventional plant breeding

and crop physiology have had limited success in building and deploying tolerance to climatic stresses in the developing world. Recent advances in transgenic approaches to provide enhanced drought tolerance hold promise to move forward. The stress-regulated expression of *DREB1A* gene by the *rd29A* promoter has shown to confer tolerance to drought, low temperatures, and salinity in *Arabidopsis*, rice, and wheat (Dubouzet *et al.*, 2003; Pellegrineschi *et al.*, 2004). Other gene *XVSAP1* derived from the resurrection plant *Xerophyta viscosa* Baker is implicated in resistance to abiotic stress resistance (Garwe *et al.*, 2003). We anticipate that this will be a useful strategy to adopt for banana. Drought resistant banana varieties will extend the geographic spread of banana production in Africa.

3.2 Addressing Risks and Concerns

Before release, any new banana GM varieties will go through an environment and food safety analysis, in addition to variety registration procedures. Several African countries, where GM banana research is in progress, are signatories to the Cartagena Protocol on Biosafety, which deals with the conservation of biological diversity and the equitable sharing of benefits from the use of genetic resources. The Protocol seeks to protect biological diversity from potential environmental risks posed by living modified organisms (LMOs) and GMOs resulting from modern biotechnology, taking into account risks to human health and focusing on trans-boundary movement of LMOs.

There is currently no scientifically accepted evidence to suggest that transgenic crops *per se* are any more or less toxic or allergenic than their conventionally bred counterparts (Ruibal-Mendieta and Lints, 1998). Since banana is an important food and fodder crop in Africa, any effort to genetically modify the crop with eventual goal of producing food and feed, novel genes ought to be made in the context of social, economic, and political considerations of the new technology and proceed in a safe and highly responsible manner. Accordingly, several studies will be conducted on the transgenic banana to guarantee that the product placed on the market as food or feed is safe. In particular, the compositional analysis to ascertain that

transformed banana is substantially equivalent to isogenic nontransformed plants, nutritional trials for digestibility in model animals to confirm nonallergenicity using standard protocols, toxicity of transgenic banana to confirm nontoxicity in model animals and indicator species and finally acute gavage mouse studies to confirm nontoxicity will be performed before release of the GM varieties.

There are potential benefits to human health and well-being by using transgenic bananas. The insertion of genes for vitamins into staple crops such as banana can enhance their nutritional value. Genetic engineering could be used to develop pharmaceuticals and vaccines in plants, decreasing the risk of adverse reactions, and enabling faster vaccination of large populations.

A variety of concerns have been expressed regarding the impact of transgenic crops on the environment. The major potential risks of GM crop to the environment and wildlife is the gene flow. Banana is a sterile, vegetatively propagated plant lacking wild relatives in Africa meaning that the potential for outcrossing transgenic banana with other banana cultivars or other crops is negligible.

Commercial banana production requires application of large amounts of pesticides that pollute the environment, and whose residues accumulate in plantation workers. Therefore, it would be ethically justifiable to produce a transgenic banana variety that would allow for a reduction in pesticide application and a subsequent improvement in human health. Genetically engineered pest and disease resistance could reduce the need for pesticides and other chemicals, thereby decreasing the environmental load and farmers' exposure to toxins. The development of bananas resistant to pests, disease, and extreme weather, decreasing the risk of devastating crop failure will be potentially useful contributions to sustainable farming. Although weighing risks and benefits is necessary, it is neither easy nor the sole concern in considering the ethics of agricultural biotechnology.

In Western countries where food supplies are abundant and incomes are high, people can afford to be critical about the introduction of new agricultural technologies and production processes about which they are unsure. In developing economies, by contrast, the benefit/cost ratio is very different. Many food-insecure people in

developing countries live in rural areas, earn a significant share of their income from agriculture, and meet a substantial share of their food needs from their own production. For them, increasing agricultural productivity and thereby real income is a high priority. And for the urban poor in those countries, anything that lowers the effective price of basic foods is highly desirable.

Bananas and plantains are staple food crops for over 100 million people in sub-Saharan Africa and over half a billion worldwide. Despite its importance, there are many diseases and pests severely effecting banana production and threatening livelihood of millions of farmers. The production of nematode, fungus, bacterial, and virus-resistant transgenic will be a major benefit for farmers. It may also be possible to incorporate other characteristics such as drought tolerance, thus extending the geographic spread of banana and plantain production, and thus contributing significantly to food security and poverty alleviation in developing countries.

3.3 Expected Technologies

Research in the field of transgenic improvement and functional genomics in banana is constrained by low efficiency and cultivar-specific transformation systems and therefore, an efficient transformation protocol is crucial. Currently, the transformation system based on cell suspension cultures is most commonly used but development of cell suspension is time consuming and cultivar specific. Several labs are trying to develop an efficient and rapid transformation system that can be applied to broad range of cultivars.

Successful genetic transformation requires not only efficient gene delivery, but also an efficient selection system to distinguish transgenic from nontransgenic events. Several different selection strategies have been used in bananas, mainly using antibiotic or herbicide resistance genes. However, there have been concerns over the use of these selective markers. Concerns have been raised that the selectable marker genes could be transferred into microbes and increase the number of resistant pathogens, or that horizontal transmission of the marker gene into wild relatives may result in weedy pests (Nap *et al.*, 1992). Several strategies to eliminate marker genes have been employed.

Co-transformation using binary vectors carrying two separate T-DNAs was used for rice transformation and the segregation of the transgenes in the progeny allowed the retrieval of marker-free plants (Komari *et al.*, 1996). Becker *et al.* (2000) has demonstrated co-transformation in banana, which should be used further. Transient expression of the *cre/loxP* site-specific recombination system (Gleave *et al.*, 1999) together with a conditional dominant lethal gene *codA* (Perera *et al.*, 1993) resulted in the elimination of marker genes from transgenic plants without sexual crossing.

Mannose has been reported as a novel selectable agent and the phosphomannose isomerase gene (*pmi*) as its suitable selectable marker (Joersbo and Okkels, 1996). Recently, transgene removal systems denoted as MAT vectors have been developed to generate marker-free transgenic plants through a single step transformation (Ebinuma *et al.*, 1997). The introduction of the *pmi* during transformation makes this an ideal system for positive selection whereby plants containing the gene are able to survive on a medium containing mannose. This can be potential selection marker for banana transformation.

Currently, the strong constitutive promoters are routinely used for banana transformation but tissue-specific promoters might be better especially for developing pest resistant varieties. The most useful types of promoters for nematode control strategies are those providing root-specific gene expressions since roots are not consumed in bananas. There is a value in limiting spatial and temporal patterns of expression of an effector to the locale of the parasites and away from food parts of the plant. Root-specific promoters would serve this ideal and drive effective resistance against a number of nematode species. Feeding site-specific promoters would be of more specialized value against particular nematode species. Several root-specific promoters of value for nematode control have been identified at the University of Leeds, UK. Ideally the optimal promoter for nematode control would exhibit the correct spatial and temporal expression pattern only within roots and throughout parasitism.

In order to accelerate efforts in producing improved varieties of banana and plantain, a Global *Musa* Genomics Consortium was established in 2001 with the goal of assuring the sustainability of banana as a staple food crop by developing

an integrated genetic and genomic understanding, allowing targeted breeding, transformation, and more efficient use of *Musa* biodiversity. Basically, the consortium aims to apply genomics to the sustainable improvement of banana and plantain. The consortium believes that genomic technologies such as analysis and sequencing of the banana genome, identification of its genes and their expression, recombination and diversity can be applied for the genetic improvement of the crop (Frison *et al.*, 2004). Genetic and physical mapping of the *Musa* genome will make it possible to isolate genes that can be used in genetic transformation.

Currently, no transgenic bananas and plantains are commercially available; however there is enormous potential for genetic manipulation of *Musa* species for disease and pest resistance using the existing transformation systems. Using molecular techniques, novel genes encoding agronomically important traits can be identified, isolated, characterized, and introduced into cultivars via genetic transformation. The use of appropriate gene constructs may allow the production of nematode, fungus, bacteria, and virus-resistant plants in a significantly shorter period of time than using conventional breeding, especially if several traits can be introduced at the same time. Long-term and multiple disease resistance can be achieved by integrating several genes with different targets or modes of action into the plant genome. Technically, this can be done either in several consecutive steps or simultaneously. Plant biotechnology has the potential to play a key role in the sustainable production of *Musa*.

3.4 Intellectual Property Rights (IPR), Public Perceptions, Industrial Perspectives, Political and Economic Consequences

Most innovations in biotechnology are developed using the knowledge or technologies generated from previous innovations. Many plant biotechnology products or techniques are “modular” in that they are assembled from a number of previously developed technologies/transgenes, each of which may be subject to a separate patent. The commercialization of many proprietary biotechnology products is typically contingent on other proprietary biotechnology products or

processes and in particular on agreements between IPR holders regarding the relative contributions of different proprietary technologies to the product in question. Many biotechnology products (e.g. transgenic seeds or transgene constructs) now have a complex IPR pedigree because a large number of proprietary products or processes are involved in developing the product.

The current generation of transgenic bananas and their testing, however, highlights some problems that need to be avoided in future. Some genes of agronomic interest were owned by the industry, and it took much effort by the Catholic University of Leuven before these genes could be used freely for plantain and cooking bananas. Therefore, it is urgent that a mechanism is put in place whereby an authority at the global level will interact with the industry to negotiate access to protected technologies for developing countries. However, in the case of food production by smallholders like banana and plantain, it is absolutely necessary that technologies are royalty free and that the farmers should have privilege to save seed (or planting material) for subsequent replanting and distributed from farmer to farmer without any financial return to the industry. It is clear that delivery of GM products to smallholder farmers in Africa will be expensive. Remington and Bramel (2004) had described handling of GM seeds for small farmers in Africa through partnership with NGOs.

Currently, a number of institutions in Africa are focused on developing and promoting biotechnology for farmers (CBI, 2003). Foundations, international organizations like CGIAR, NGOs, and national governments are promoting the potential benefits of biotechnology in addressing the critical need to increase food production in Africa. Several research networks have been established to promote biotechnology research in crops such as cassava, banana, rice, sweetpotato, and cowpea that can benefit the poorest farmers in Africa.

Donor initiatives are promoting research and development of biotechnology products with public/private partnerships, and donors and international organizations initiatives will strengthen biosafety regulation and technical expertise in developing countries to enhance the application of biotechnology products. Novel partnerships are being formed between the private sector, donors,

and nonprofit organizations to find common and acceptable grounds. For example, many donor agencies are providing ways for North–South partnerships to open up African markets in a mutually beneficial and sustainable manner. African Agricultural Technology Foundation (AATF) was launched in 2003, whose mission is to acquire technologies through royalty-free licenses along with associated materials and know-how for use on behalf of SSA's resource-poor farmers, while complying with all laws associated with the use of these technologies. AATF has been instrumental in facilitating technology transfer negotiations whereby proprietary biotechnologies have been made available to Africa. Recently, IITA has negotiated royalty-free license from Academia Sinica, Taiwan through AATF for access of technology for bacterial wilt resistance. AATF has signed the licensing agreement with Academia Sinica, Taiwan for access to the *pflp* gene for use in banana for the commercial production of varieties resistant to banana bacterial wilt in all of sub-Saharan Africa and granted a sublicense to IITA for developing the improved varieties.

In view of the tremendous losses incurred by smallholder *Musa* farmers due to pest and disease attack, and the economic, environmental, and health costs associated with plant protection measures in large-scale commercial plantations of banana, it is very much to be hoped that the remaining technical, intellectual property, and regulatory obstacles to the deployment of transgenic bananas and plantain can soon be overcome. It is not anticipated that transgenic varieties will threaten the diversity of existing varieties grown by banana farmers. Rather, studies in East Africa suggest that varieties modified for pest or disease resistance will be incorporated into the range of varieties already grown as part of a strategy to reduce risk, provide multiple products, and satisfy varying tastes. In the meantime, various biotechnology techniques are already contributing to conventional breeding efforts and are expected to become even more effective in this area as genetic maps and markers are refined. The use of tissue culture plants is already contributing to the development of novel production systems for smallholder farmers and, as part of a balanced program of deploying biotechnology techniques cost effectively in the developing countries, tissue culture is expected to be much more widely used

in increasing the productivity and sustainability of such systems in the future.

Pineapple

Hian-Lien Ko, Garth M. Sanewski and Mike K. Smith

*Department of Primary Industries & Fisheries, Maroochy Research Station, Nambour,
Queensland, Australia*

1. INTRODUCTION

1.1 History, Origin, and Distribution

Pineapple, *Ananas comosus* (L.) Merr., is native to South America and was first seen by Europeans when Christopher Columbus landed on an inhabited island in the Caribbean that he named Guadalupe on his second voyage in 1493 (Collins, 1948). Little is known regarding the domestication of the pineapple before 1493 except that at that time the plant was already in cultivation throughout the West Indies, and most likely on the mainland of Brazil (Collins, 1951). Although widespread in cultivation and in the wild, work by Duval *et al.* (2005) with restriction fragment length polymorphism markers of chloroplast DNA supports the hypothesis of a center of diversity and hence origin of the domesticated pineapple in Guyana, north of Brazil. The *Ananas* genus is, however, generally considered indigenous to Brazil and northern Paraguay (Duval *et al.*, 2003). In early times, the pineapple was used extensively by the Amerindians of these regions as a fresh fruit, for making wine and twine, and for medicinal purposes (Collins, 1949, 1951; Leal and Amaya, 1991; Leal and Coppens d'Eeckenbrugge, 1996). From the Americas, pineapples were taken back to Europe to be grown in the hothouses of the wealthy gentry but eventually they spread around the globe predominately by seafaring Portuguese traders. Pineapple is now grown in most tropical and subtropical countries.

Extensive collections of wild germplasm are held in Brazil, Martinique, and Venezuela (Ferreira and Cabral, 1993; Coppens d'Eeckenbrugge *et al.*, 1997).

1.2 Botanical Description

The pineapple is a monocotyledonous, perennial, herbaceous plant with crassulacean acid metabolism (CAM) photosynthesis. The CAM system of photosynthesis gives the plant good water-use efficiency and the ability to withstand extreme water deficit (Malezieux *et al.*, 2003). The fruit, a sorose of multiple fused fruitlets, is borne on the terminal. New shoots capable of producing another fruit arise from axillary buds (Okimoto, 1948; Coppens d'Eeckenbrugge and Leal, 2003).

1.2.1 Taxonomy

There are three subfamilies within the family Bromeliaceae—Bromelioideae, Pitcairnioideae, and Tillandsioideae. The subfamily Bromelioideae contains 27 genera and 536 species (Brown and Gilmartin, 1986) including the pineapple genus *Ananas*. The closely related genus, *Pseudananas*, contains the single species *P. sagenarius*. The taxonomy of pineapple has been reviewed several times but the most enduring is the current system based on the key of Smith and Downes (1979). In this system, the genus *Ananas* contains seven

species—*A. comosus*, *A. ananassoides*, *A. nanus*, *A. bracteatus*, *A. parguazensis*, *A. fritzmuelleri*, and *A. lucidus*. This classification is, however, based largely on traits that are governed by only a few genes or that are continuous and strongly influenced by the environment (Leal and Coppens d'Eeckenbrugge, 1996). Molecular studies (Duval *et al.*, 2001, 2005) indicate gene flow and continuous variation between the species with no clear indicators of speciation. All these species are also interfertile. It has been proposed by Coppens d'Eeckenbrugge and Leal (2003) and supported by Duval *et al.* (2005) that all the seven species of *Ananas* should be reclassified as varieties within the one species, *A. comosus*, and that *P. saganarius* should be reclassified as a species of *Ananas* called *A. macrodontes*.

The wild species, *A. ananassoides*, shows the greatest level of polymorphism and is considered the ancestor of all domesticated genotypes. *A. fritzmuelleri* appears closely related to *A. macrodontes*, and *A. lucidus* appears closely related to *A. ananassoides*. *A. bracteatus* appears close to *A. fritzmuelleri* and *A. macrodontes*.

1.2.2 Genetics

A. comosus has a diploid chromosome number of 50 with small chromosomes (Collins and Kerns, 1931; Marchant, 1967; Brown and Gilmartin, 1986; Brown *et al.*, 1997). Within *Ananas*, triploid, tetraploid, and heteroploid varieties exist (Capinin and Rotor, 1937; Collins, 1960). Triploids arise when unreduced egg gametes are fertilized by normal haploid pollen (Collins, 1933). *P. saganarius* is a naturally occurring tetraploid (autopolyploid) with 100 chromosomes (Collins, 1960; Duval *et al.*, 2005). Triploids are generally more vigorous than diploids (Collins, 1933) and can be commercially acceptable (Leal and Coppens d'Eeckenbrugge, 1996), but tetraploids are generally inferior to triploids and diploids. While very vigorous in growth, tetraploids produce small fruit with lower sugar content (Kerns and Collins, 1947).

Collins and Kerns (1931) reported that meiosis was regular in *A. comosus* and only rarely were there irregularities, such as lagging chromosomes or abnormal tetrads. However, Coppens d'Eeckenbrugge *et al.* (1993) demonstrated a low

level of pollen fertility (low production and poor viability) in *A. comosus* that could be at least partly attributed to meiotic irregularities.

Differences in size of mature pollen grains are common (Collins and Kerns, 1931). This size variation has been associated with meiotic irregularities (Bhowmik and Bhargabati, 1975; Bhowmik, 1977). Large or giant pollen cells are thought to contain the diploid number of 50 chromosomes (Collins, 1960).

The number of ovules per flower varies considerably within *A. comosus* from 16–27 in the Queen group to a maximum of 71 in the Perolera group. Rao and Wee (1979) reported 24–84 ovules per flower for the different *A. comosus* types. Few of these ovules develop into seed (Coppens d'Eeckenbrugge *et al.*, 1993). Even where highly compatible varieties are manually hand pollinated, there are usually no more than approximately 20 seeds per flower ever obtained in *A. comosus* types (Sanewski, unpublished data). Cleistogamy can occur in some varieties of *A. comosus* (Chan *et al.*, 2003).

Most varieties of *A. comosus* are self-incompatible due to the inhibition of pollen tube growth in the upper third of the style (Kerns, 1932), which is gametophytically controlled by a single locus with multiple alleles (Brewbaker and Gorrez, 1967). Some cultivars exhibit partial incompatibility (Cabral *et al.*, 2000). The primitive types, *A. ananassoides*, *A. bracteatus*, and *P. saganarius*, are either partially or completely self-compatible.

1.3 Economic Importance

The pineapple is a versatile plant and yields many products. In addition to the familiar canned, dehydrated, and juice products, the fruit can also be minimally processed into a fresh but peeled, cored, and sliced product. The peel and core refuse from processing are often used as cattle feed. The leaf has long been used for its fiber, which can be made into a range of products from high-quality cloth and paper to composite plastics (Hepton and Hodgson, 2003). The plant is occasionally used for ornamental purposes and a small market exists for the flowers of some genotypes.

Crude extracts from the fruit, stem, and leaves yield, among other compounds, several

proteinases, most notably bromelain, which has a range of pharmaceutical uses based only partly on its proteolytic activity. Activities of bromelain include antiedematous, anti-inflammatory, antithrombotic, fibrinolytic, and immunomodulatory (Maurer, 2001).

World production of pineapple was estimated at over 18.2 million tonnes in 2006 (FAOSTAT, 2008). While much of the world trade in pineapple is as processed product, approximately 70% of production is consumed fresh in the countries of origin (Rohrbach *et al.*, 2003). The leading producers are Thailand, the Philippines, Costa Rica, China, Brazil, and India. The export value of pineapple and pineapple products from the producing countries was over US\$665 million in 2004 (FAOSTAT, 2008). Most of the world's export production (about 70%), and most of the canned pineapple (about 95%), comes from a single cultivar, Smooth Cayenne (Rohrbach *et al.*, 2003).

1.4 Traditional Breeding

It is generally recognized that the indigenous people of South America contributed substantially to the domestication of the pineapple (Leal and Coppens d'Eeckenbrugge, 1996) probably through the selection of spontaneous mutations expressing desirable traits. The types found growing in and around villages usually exhibit desirable traits such as improved palatability, improved fruit size, seedlessness, smooth leaves, and, in some cases, improved leaf fiber properties, which are not commonly found in wild types (Collins, 1951; Coppens d'Eeckenbrugge *et al.*, 1997).

The first major hybridization program was conducted by the Pineapple Research Institute (PRI) in Hawaii in several phases from 1917 to 1972 (Wortman and Kerns, 1959; Williams and Fleisch, 1993). The objectives initially were to replace Smooth Cayenne as a processing cultivar but eventually expanded to include fresh fruit. Specific objectives included varieties more suited to summer, winter, tropical conditions, high-density plantings, mechanical harvesting, and heart and root rot resistance (Smith, 1965). Both intra- and interspecific crosses were conducted and selection encompassed many aspects of productivity, fruit quality, and pest and disease

resistance. The PRI program developed cultivars more resistant to root and heart rot, pink disease, fruit marbling, fruitlet core rot, and with some tolerance to mealybug wilt and root knot and reniform nematodes. Resistance to the physiological disorder, blackheart, was also demonstrated as well as improvements in ascorbic acid content, yield, canned product quality, fibrosity, and higher or lower acidity (Dull, 1965; Rohrbach and Pfeiffer, 1975; Williams and Fleisch, 1993; Rohrbach and Schmidt, 1994). Despite the considerable effort that was expended in this breeding effort, few varieties were commercialized at that time. Most varieties eventually exhibited a fault that precluded large-scale commercialization (Williams and Fleisch, 1993). In more recent years, the declining margins in processed pineapple have seen an increase in interest in the fresh fruit sector. There has consequently been a reappraisal of PRI varieties and at least four varieties have now been commercialized to some extent for the fresh fruit market.

Many pineapple-producing countries now conduct hybridization and selection programs. The most notable programs exist in Australia, Brazil, Martinique, Malaysia, and Taiwan. Most breeding has utilized the different varieties of *A. comosus* such as Cayenne, Queen, Mordilona, Spanish, and Pernambuco or hybrids thereof to produce segregating populations of seedlings for screening and selection. Objectives are usually aimed at suitability for the fresh fruit market and, in some cases, include additional characteristics such as resistance to Fusariose caused by *Fusarium moniliforme* var. *subglutinans* (Cabral *et al.*, 1993, 1996; Hidalgo *et al.*, 1998), improved eating quality (Sanewski, 1998), reduced incidence of translucency (Leal and Coppens d'Eeckenbrugge, 1996), and a shorter cropping cycle (Chan and Lee, 2000).

Most domesticated varieties of the pineapple are considered highly heterozygous (Chan, 1989; Sanewski, 1998). Most pineapple hybridization programs have, therefore, achieved only limited success despite considerable effort (Chan *et al.*, 2003). Selfing has been proposed as a strategy to increase the level of homozygosity and purge undesirable recessive alleles from the breeding gene pool (Coppens d'Eeckenbrugge *et al.*, 2005). However, the low level of self-compatibility in most commercial varieties makes this somewhat

impractical. Lower levels of inbreeding may, therefore, be more appropriate.

Clonal selection has also been used to improve varieties, particularly Smooth Cayenne (Collins and Kerns, 1938; Chan *et al.*, 2003).

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

The high level of heterozygosity in domesticated pineapple has been the main cause of the very limited success in hybridization breeding programs worldwide. Sexual recombination of the many chromosomes coupled with a large number of selectable characteristics has meant that improvements in some characters usually come at the expense of a decline in others. Nevertheless, new hybrids specifically aimed for the domestic fresh fruit markets have been developed. A first result of these efforts has been the successful introduction of a low-acid cultivar by Del Monte from Costa Rica into European and American markets (Rohrbach *et al.*, 2003). However, sufficiently significant improvements in some characteristics, such as resistance to nematodes or mealybug wilt, have not been possible, because the resistance systems do not exist at a useful level within the *Ananas* gene pool.

Smooth Cayenne is the main variety used for processing and has been grown on a large-scale commercial basis throughout the world since the early 1900s. Production and processing practices are, therefore, highly developed for Smooth Cayenne. For new cultivars to be acceptable to growers and processors, new cultivars must be very similar to Smooth Cayenne in agronomic and processing attributes. Because Smooth Cayenne is highly heterozygous and imparts considerable transgressive recombination, conventional hybridization is unsuitable for developing new processing types if the outcomes are to be achieved in a reasonable time frame. Transformation with engineered genes is ideally suited to improving Smooth Cayenne. It should allow specific changes to be made to targeted genes without rearranging the entire genome.

Although the length of time and costs of the initial transformation research necessary to clone the suitable genes and produce the transgenic

plants can be high, once the plants have been obtained the process is relatively cheaper and more straightforward than conventional breeding. Extensive field trials at multilocal sites and factory evaluation will still be necessary to obtain the best plant for commercial release.

2. DEVELOPMENT OF TRANSGENIC PINEAPPLES

Methods involving the introduction of recombinant DNA to pineapple cells and tissues are via *Agrobacterium tumefaciens*-mediated transformation and direct gene transfer through microprojectile bombardment. Reviews including sections on genetic engineering and molecular genetic improvement of pineapple have been published (Smith *et al.*, 2002b, 2005; Botella and Smith, 2008). However, 2006 saw the publication of a number of important studies on pineapple transformation. For instance, two groups employed biolistics technology to introduce economically important traits, i.e., herbicide resistance (Sripaoraya *et al.*, 2006a, b) and blackheart resistance (Ko *et al.*, 2006). Other groups focussed on using *Agrobacterium* infection techniques (Yabor *et al.*, 2006), also Firoozabady *et al.* (2006) and Trusov and Botella (2006) who reported on further evaluation of the expression of a useful 1-aminocyclopropane-1-carboxylate (ACC) synthase gene for fruit ripening.

2.1 Donor Genes

2.1.1 Source

A limited range of donor genes have been employed for pineapple transformation. To optimize transformation conditions, usually the β -glucuronidase (*gus* or *uidA*) reporter gene, originating from *Escherichia coli*, has been used. The green fluorescent protein (*gfp*) gene from *Aequorea victoria* has also been used to monitor transformation (Graham *et al.*, 2000a; Ko *et al.*, 2006), with the advantage that analysis of expression of this gene can be monitored over time in the same tissues as it is nondestructive.

As selectable marker genes, both herbicide-resistant genes and antibiotic-resistant genes are used. The most common herbicide-resistant genes introduced to pineapples are the *bar* gene (Sripaoraya *et al.*, 2001, 2006a, b; Yabor *et al.*, 2006) and the *surB* gene. The *bar* gene is obtained from *Streptomyces hygroscopicus* and inactivates phosphinothricin (PPT), conferring resistance to the herbicide bialaphos, but it also converts glufosinate ammonium, the active component of the commercially manufactured herbicide BastaTM, to an inactive form. The acetolactate synthase *surB* gene is derived from tobacco and confers resistance to chlorsulfuron, a sulfonylurea (Firoozabady *et al.*, 2006). The neomycin phosphotransferase (*nptII*) gene, conferring resistance to the antibiotics kanamycin, paromomycine, and geneticin (G418), is also extensively used.

Only a few economically important transgenes have been introduced into pineapple thus far. One of the most studied are the ACC synthase genes (*acacs1*, *acacs2*, and *acacs3*; Botella *et al.*, 2000; Trusov and Botella, 2006) to control natural flowering and to delay ripening. These genes have been isolated from the pineapple plant itself. The ACC synthase gene from pineapple is expressed in meristematic cells and activated to induce flowering under certain environmental conditions (low temperatures and photoperiod). Although pineapple is a nonclimacteric fruit, ethylene is still believed to play a significant role during ripening. Considering harvesting costs take up 34% of the total production costs, synchronized flowering will minimize harvesting and production costs and hence improves the competitiveness of the industry. To enhance *acacs* gene expression, a complex promoter–leader–intron structure was inserted at the 5' end of the transgenes, described by Firoozabady *et al.* (2006) and Trusov and Botella (2006). A *waxy* gene leader derived from *Zea mays* was fused to the *acacs* gene and an intron derived from the *CHS-A* gene of *Petunia hybrida* was inserted into the central region of the *waxy* leader.

Polyphenol oxidase (PPO) genes to control blackheart (*PINPPOI*; Stewart *et al.*, 2001) have also been isolated from blackheart-affected fruit. Blackheart occurs when temperatures in subtropical pineapple growing areas reach below 20 °C combined with lower light intensities in the

winter months. Alternatively, this occurs during cold transport of fruit followed by higher storage temperatures, of relevance in export of fresh fruit. The injury is evident around the core of the fruit and is, therefore, not detectable on intact fruit, resulting in wastage and decreased consumer confidence in the fruit. The *PINPPOI* gene has been used in sense, antisense, and hairpin constructs in an effort to silence PPO expression in pineapple fruit (Ko *et al.*, 2006).

Espinosa *et al.* (2002) and Yabor *et al.* (2006) included two antifungal genes (*chi* and *ap24*) in their studies, in an attempt to reduce losses caused by *Phytophthora nicotianae* var. *parasitica*. The class-I chitinase gene originates from *Phaseolus vulgaris*, while the *ap24* gene is derived from *Nicotiana tabacum*. Their studies are based on degrading fungal cell wall compounds and destabilizing fungal membrane potential. The *gluc* gene is a class-I tobacco β -1,3-glucanase gene.

2.1.2 Designing transgenes

A study on promoters was reported by Graham *et al.* (2000a), whereby transient assays using the biolistic gene delivery technique were monitored to define the activity of a number of promoters in various pineapple tissues. Promoter-*gus* gene fusions were delivered into callus, leaf, and fruit tissues and β -glucuronidase (GUS) activity determined after 48 h. Constructs containing the *Ubi-1* promoter showed strong activity in all tissues, as did the cauliflower mosaic virus (CaMV) 35S promoter. Other promoters to drive selectable marker genes were also examined and subclover stunt virus (SCSV) and banana bunchy top virus promoters were found to drive high-level marker gene expression, particularly in callus tissue.

A summary of genes, promoters and terminators used in published pineapple transformation studies is given in Table 1.

Firoozabady and Gutterson (1998) and Firoozabady *et al.* (2006) described the use of a disarmed *Agrobacterium* strain, C58, which was superior for carrying a binary vector containing the *surB* gene with a number of different plasmids tested. *Agrobacterium* strains LBA4404 and EHA101 were also used, but these yielded a

Table 1 Summary of published transgenes introduced into transformed pineapple plants

much lower level of GUS activity. The plasmids contained the following constructs:

- *nptII* gene and *surB* gene both driven by ubiquitin (*Ubi-1*) promoter from *Z. mays* allowed selection of transgenic tissue by two agents,
- *gus* gene driven by *Smas* promoter and *surB* gene driven by *Ubi-1* promoter were constructed to monitor DNA delivery and transformation by GUS expression and to apply selection using chlorsulfuron,
- *surB* gene driven by *Ubi-1* promoter and ACC synthase gene induced in fruit during ripening (*acacs2*) driven by *Smas* promoter to introduce fruit ripening control gene into pineapple and to apply chlorsulfuron selection,
- ACC synthase gene expressed in meristem (*acacs3*) driven by an enhanced CaMV 35S promoter to control precocious flowering.

Agrobacterium strains LBA4404 and AT2260 were used by Espinosa *et al.* (2002). The plasmids contained the following constructs:

- *nptII* gene under control of *nos* promoter, as well as *gus (uidA)* gene and *hph* gene conferring resistance to hygromycin, both driven by CaMV 35S promoter,
- *chi* gene under control of a hybrid *ocs*-CaMV 35S-*rice actin I (pA5)* promoter, plus the *ap24* gene driven by CaMV 35S promoter for fungal tolerance, and the *bar* gene under control of *Ubi-1* promoter,
- *chi* gene under control of *pA5* promoter, plus *gluc* gene under control of CaMV 35S promoter, and the *bar* gene driven by *Ubi-1* promoter.

Graham *et al.* (2000a, b) used *Agrobacterium* strain AGL0. This strain was transformed with

binary vectors containing constructs designed to express a number of genes. The following constructs were used in their studies:

- selectable marker gene *nptII* driven by *nos* or SCSV4 promoter and SCSV5 terminator,
- *gus* reporter gene driven by CaMV 35S promoter,
- *gfp* gene, with the CaMV 35S promoter operably linked to the gene.

Based on findings of Graham *et al.* (2000a) and taking intellectual property (IP) issues with available promoters into consideration, the following constructs for biolistics transformation were then prepared and used by Ko *et al.* (2005, 2006):

- two plasmids expressing the *nptII* selectable marker gene driven by CaMV 35S promoter and terminator, or controlled by segment 4 promoter and segment 7 terminator coding sequences from SCSV, cloned into the polylinker site of the expression caset pART7 (Gleave, 1992),
- two *gus* marker gene constructs, one driven by CaMV 35S constitutive promoter and the octopine synthase region of *A. tumefaciens* (*ocs*) terminator, the other controlled by SCSV4 promoter and SCSV5 terminator,
- *gfp* reporter gene under control of the maize *Ubi-1* promoter and the nopaline synthase region of *A. tumefaciens* (*nos*) terminator,
- pineapple *PINPP01* gene in a sense orientation (*ppo*) controlled by CaMV 35S promoter and *ocs* terminator, or in a sense–antisense orientation including a hairpin RNA interference (RNAi) intron (*opp.i.ppo*), whereby CaMV 35S promoter and *nos* terminator are driving the *opp* gene, and *Ubi-1* promoter and *ocs* terminator controlling the *ppo* gene.

According to Smith *et al.* (2000) using the hairpin RNAi strategies greatly increases inactivation of gene expression.

Target genes were co-transformed with the selectable marker gene in a 3:1 molar ratio.

For the development of herbicide resistant pineapple plants, Sripaoraya *et al.* (2001) transformed pAHC25 containing the *gus* (*uidA*) reporter gene and the *bar* selectable marker gene, both driven by maize *Ubi-1* promoter with its first

exon and first intron. Transgenic plants were tested by treatment with Basta.

2.2 Methods Employed

Transformation efficiencies of pineapple through either particle bombardment or *Agrobacterium*-mediated gene delivery are generally around or below 5%, based on the number of transgenic events per number of explants subjected to the transformation process. Firoozabady *et al.* (2006) reported a transformation efficiency of up to 60% for transgenic lines of the Smooth Cayenne cultivar “Champaka” containing the *acacs* genes expressed in the ripening of pineapple fruit. This transformation efficiency was based on the number of transgenic lines produced per weight of cells subjected to treatment.

2.2.1 *Agrobacterium*-mediated transformation

Firoozabady and Gutterson (1998) and Firoozabady *et al.* (2006) described the use of two embryogenic systems for transformation of pineapple—a friable embryogenic cell cluster (ECC), with potential for somatic embryo production, and a chunky nondispersible embryogenic tissue (ET), which consists of a cluster of immature somatic embryos. After 2 to 3 days of co-cultivation in the dark, explant material was placed on a recovery medium without selection pressure for 5–12 days. ET needs sonication and vacuum infiltration to allow the bacteria to penetrate into the tissue. Embryogenic tissue was then subjected to a sequence of treatments on maturation media containing 1 mg l⁻¹ BA (6-benzyl adenine) and an increasing concentration of chlorsulfuron for 3–4 months until globular embryos were produced or germination took place. Shoot clusters were then produced, followed by shoot multiplication. Up to 90% of treated tissue produced shoots within 4 months. Shoot elongation occurred on a medium containing 0.2 mg l⁻¹ BA, followed by root initiation on 1/2 MS + 0.5 mg l⁻¹ each of α -naphthalene acetic acid (NAA) and indole-3-acetic acid (IAA), and activated charcoal. Shoot clusters were maintained indefinitely in liquid medium containing 1.5 mg l⁻¹ each of BA and NAA, with monthly subcultures.

Selection was continued throughout the regeneration process to eliminate chimeric plants.

Ko *et al.* (2005), on the other hand, co-cultivated *in vitro*-grown leaf bases with *Agrobacterium* bacterial suspension under 5 min of vacuum infiltration at 27–29" Hg, to assist with penetration into the plant cells. Co-cultivation occurred for a period of 3 weeks under a natural daylight cycle, followed by selection on a medium containing 50 mg l⁻¹ G418 with monthly subcultures twice, then increasing the G418 concentration to 100 mg l⁻¹ (Graham *et al.*, 2000b). After 3 to 5 months, transformed organogenic callus was produced, and after a further 3 to 4 months, shoots were regenerated from the transgenic callus. In total 63 transformed lines were recovered, with an average transformation efficiency of 2.4%. Compared to a biolistics technique (Ko *et al.*, 2006) this method only requires tissue to go through one callus phase for 4 to 5 months, thereby minimizing the chance for somaclonal variation. Furthermore, to produce sufficient explant callus to achieve similar numbers of transgenic lines produced through the microprojectile bombardment strategy (see Section 2.2.2), it would take an additional 12 months of *in vitro* culture.

The introduction of antifungal genes *chi* and *ap24* into callus tissue has been achieved by Espinosa *et al.* (2002) and Yabor *et al.* (2006), with up to 6.6% efficiencies of transgene plant recovery reported. Espinosa *et al.* (2002) introduced the application of temporary immersion bioreactors (TIBs) in the selection and micropropagation phase of the process. Following the initial studies, Yabor *et al.* (2006) applied the system to study biochemical side effects of *Agrobacterium*-mediated pineapple genetic transformation on the plants. The presence and amounts of compounds related to the pathways describing responses to stress and photosynthesis were measured.

In all *Agrobacterium*-mediated experiments, care should be taken to prevent the bacteria from overgrowing the tissue sample during co-cultivation, while after the relevant co-cultivation time, the bacteria needs to be killed without the explants being affected. Shackelford and Chlan (1996) and Singh Gill *et al.* (2004) reported on experiments performed to determine which antibiotics are most efficient for this purpose. Different strains of *Agrobacterium* appear to have different sensitivities to different antibiotics, while

some antibiotics were found to be detrimental to callus growth by decreasing transformation efficiencies or interfering with the regeneration process (Firoozabady *et al.*, 2006). Cefotaxime appeared to be the most popular antibiotic used in the reported studies.

2.2.2 Biolistics transformation

Biolistics has also been used to good effect with pineapple transformation. Early studies by Nan *et al.* (1996) reported on transient expression experiments using the *gus* reporter gene and various promoters on a variety of tissues (parts from crowns, slips, and lateral buds of field-grown plants); however, no further reports of production and evaluation of transformed plants have been published. Recent studies by Ko *et al.* (2006) have described stable integration of genes introduced by microprojectile bombardment of callus. The *PINPP01* gene was isolated and used in a construct that was delivered to 17–35-weeks-old "Smooth Cayenne" callus cultures by way of co-bombardment with a plasmid conferring *nptII* resistance, using G418 as the selective agent. From four experiments, each bombarded with the *gus* or *gfp* constructs, 15 independent transgenic events each were produced, equaling to an effective stable transformation efficiency of 0.21–0.85% for *gus* and a comparable 0.34–1.5% for *gfp*. The average transformation efficiency for the *ppo* construct was 0.86% (ranging from 0.2% to 2%), while that for the *opp.i.ppo* construct was 1.7% (ranging from 0.35% to 3.5%). Furthermore, each experiment using the hairpin construct produced transgenic lines, which was not the case with the various *ppo* constructs. These transformation efficiencies are acceptable, considering the high regeneration potential of 80–90% from callus cultures (Ko *et al.*, 2005).

Successful transformation of pineapple plants through the introduction of the *bar* gene into the cultivar "Phuket" was reported by Sripaoraya *et al.* (2001, 2006a, b). The target material was leaf bases arranged on an agar medium containing mannitol as a pretreatment to the plant tissue 2 h prior to bombardment. The authors argue that since introduction of transgene was achieved into cells that directly produce shoots, there are no problems with multiple transgene integration sites.

Although a transformation efficiency of up to 2.6% was achieved, all experiments were based on clones from five transformed plants, of which four were found to originate from the same transgenic event. Herbicide resistance in the crop improves weed control in the field, thereby reducing competition for available nutrients, resulting in increased fruit yields and economic returns. Furthermore, improved weed control also aids in disease-pest control, as weeds can harbor populations of mealybugs, ants, and aphids, which are known vectors of viruses causing mealybug wilt disease.

2.3 Selection of Transformed Tissue

To screen transformed tissue from nontransformed tissue after co-cultivation or bombardment, either antibiotic-resistant or herbicide-resistant cells are produced for selection purposes, while the cells also contain the gene of interest. Kill curves, based on lethal or sublethal dosage, are established by incorporating various concentrations of antibiotics or herbicides in the *in vitro* culture medium. The inhibitory or lethal effects on nontransformed tissue are then monitored.

By co-bombarding a construct containing *nptII* for kanamycin (100–500 mg l⁻¹) or G418 (50–200 mg l⁻¹) resistance and containing *hph* for hygromycin (10–50 mg l⁻¹) resistance, Graham *et al.* (2000a) found that G418 in a concentration of 100 mg l⁻¹ and hygromycin in a concentration of 50 mg l⁻¹ both inhibited callus growth. However, kanamycin was not an effective selection agent even at the highest concentration. Kanamycin tolerance of transformed pineapple tissue was also reported by Espinosa *et al.* (2002) and Firoozabady *et al.* (2006) at up to 125 mg l⁻¹ and 1000 mg l⁻¹, respectively.

A stepwise or delayed selection on the transformed tissue is usually preferred as it allows the bombarded or co-cultivated tissue to recover from the treatment. This was described by Sriporaya *et al.* (2001), where no selection pressure was applied for the first 4 weeks after bombardment, followed by the addition of 0.5 mg l⁻¹ PPT and then 1 mg l⁻¹ after 56 days postbombardment. Firoozabady *et al.* (2006), on the other hand, used 10–20 µg l⁻¹ chlorsulfuron for the first 3 weeks post-co-cultivation and then increased the concentration to 30–50 µg l⁻¹,

depending on which type of explant material was treated. They found that applying sublethal levels of selection immediately after co-cultivation reduced the rate of stable transformation events by 85–95% and application of lethal levels of selection immediately after co-cultivation, or within 20 days of a sublethal selection period, resulted in no transformed tissue being produced. Ko *et al.* (2006) elected to use 50 mg l⁻¹ G418 for two fortnightly subcultures, followed by 100 mg l⁻¹ G418 for subsequent monthly subcultures. Finally, Espinosa *et al.* (2002) and Yabor *et al.* (2006) co-cultivated tissue placed on callus proliferation media for 4 weeks before selection on 2.5 mg l⁻¹ PPT. They found that 10–20 mg l⁻¹ hygromycin suppressed shoot multiplication after 45 days in their liquid TIB system as well as on solid medium. On the other hand, the herbicide PPT inhibited multiplication of plant tissue in the liquid system at a concentration of 2.5 mg l⁻¹, while on solid medium the plant tissue was able to tolerate up to 7.5 mg l⁻¹ PPT. By treating putative transgenic plants in the TIB system with 2.5 mg l⁻¹ PPT, where the shoots were immersed for 2 min every 3 h, PPT-resistant shoots were obtained after 30 days.

2.4 Regeneration of Whole Plants

Regeneration of shoots and plants through either organogenesis or embryogenesis is a prerequisite for successful genetic engineering, but depends heavily on the original explant material used (Firoozabady and Moy, 2004), cultivar response (Firoozabady *et al.*, 2006; Sriporaya *et al.*, 2006b), and type of transgene construct introduced (Ko *et al.*, 2006). Firoozabady and Moy (2004) produced five types of embryogenic tissues and found that only one, described as ECC, was suitable for pineapple transformation. Other types of cells gave rise to pineapple plants via organogenesis or embryogenesis but produced mainly chimeric shoots, containing both transformed and untransformed cells.

Many alternative combinations of growth hormones for induction of plant regeneration have been reported. The addition of different components in different concentrations in successive developmental stages described by Firoozabady and Gutterson (1998), Firoozabady and Moy (2004), and Firoozabady *et al.* (2006) is one

of the most complex growth and regeneration media reported for pineapple transformation. The authors described the emergence of a yellowish tissue with globular structures after 4 weeks of culture of ECC in selection medium. This was followed by 4 weeks of culture on selective agent-free medium, then to medium containing 5 mg l^{-1} BA for 8 weeks, when embryo formation was induced. Maturation and germination was achieved by subculture of embryos onto medium containing 1 mg l^{-1} BA. To produce shoots embryos were transferred onto agar-solidified medium containing 1 mg l^{-1} BA for 4 weeks. Transgenic shoot clusters were then transferred back into liquid medium containing 1 mg l^{-1} BA, followed by subculture onto medium containing 0.2 mg l^{-1} BA for 4 to 10 weeks to encourage multiplication and elongation. Further maintenance and multiplication for an indefinite period of time occurred on MS medium (Murashige and Skoog, 1962) containing 1.5 mg l^{-1} BA and 0.5 mg l^{-1} NAA. Individual rooting of shoots was achieved by culturing shoots on $1/2$ strength MS to which 0.5 mg l^{-1} NAA and 0.5 mg l^{-1} IAA are added. After 2 to 4 weeks complete plants were obtained. Activated charcoal, $0.5\text{--}3 \text{ g l}^{-1}$, was added to improve growth of the transgenic plants.

In summary Firoozabady *et al.* (2006) stated that the critical factors for transformation of embryogenic cell clusters are 2 months of culture on high-sucrose medium, producing globular embryos, then a 2- to 3-month culture period on BA containing medium, which produced transgenic embryos and shoots. The authors reported that 70–90% of transgenic events produced shoots. In contrast, the regeneration media developed by Sripaoraya *et al.* (2001, 2006b) and Ko *et al.* (2005, 2006) for regeneration of transformed pineapple plants involved a simple two-step subculture.

Ko *et al.* (2005, 2006) used a method based on the regeneration studies of Rangan (1982). After transgenic callus pieces were allowed to initiate and proliferate on MS selection medium containing 10 mg l^{-1} each of BA and NAA, the tissue was subcultured onto growth hormone-free MS medium containing 5% (v/v) coconut water and 400 mg l^{-1} casein hydrolysate and the selective agent G418. Within 2 months shoot regeneration can be observed, whereby 70–90% of the transformed callus proved to be highly regenerable (Figure 1). Large-scale

Figure 1 Transgenic pineapple plants regenerating from callus via organogenesis

shoot regeneration continued within the following 4 to 8 months, whereby some independent transgenic lines regenerated more readily than others. Subsequent root production occurred on medium without plant growth hormones. Within 3 weeks of transgenic plants being cultured in individual tubes, 80% of the shoots produced long, thin, single roots, whereas inclusion of growth hormones in the medium induced the production of thick roots, which were easily damaged during transplanting to pots.

Sripaoraya *et al.* (2001, 2006b) subcultured regenerated plants emerging on the leaf bases on selection medium containing 1 mg l^{-1} each of 2,4-D and BA onto a medium containing twice the amount of the selective agent PPT (2 mg l^{-1}) and 2 mg l^{-1} BA for further multiplication. Subsequent rooting occurred on growth regulator-free medium under selection.

A novel approach to transgenic plant regeneration was described by Espinosa *et al.* (2002) and also used by Yabor *et al.* (2006), in which transformed cells were allowed to multiply initially by culturing callus on solid medium containing 0.5 mg l^{-1} BA, without any selection pressure. After 30–45 days putative regenerated transgenic plants were recovered, which were then micropropagated in their TIB liquid system using the selection treatment. However, most of the emerging shoots were reportedly not well developed, being pale yellow in color, and possibly chimeric.

2.5 Testing of Inheritance of Transgene and Effects on Transgenic Plants

2.5.1 GUS assay

By performing a standard histochemical GUS assay (Jefferson *et al.*, 1987) 24–48 h postbombardment, Sripaoraya *et al.* (2001) and Ko *et al.* (2006) were able to count the number of blue spots on the treated explant tissue, which was indicative of the number of cells that had been transformed with the *gus* marker gene. However, transient transformation frequencies are not necessarily correlated with stable transformation frequencies and much depends on the tissue type and even variety being transformed (Sripaoraya *et al.*, 2001). GUS activity was also detected in plant parts of *gus* containing transgenics *in vitro*, in the glasshouse or in the field. Although the GUS assay has been regarded as a lethal, once only test of confirming transgene expression, Firoozabady *et al.* (2006) reported that when stained pieces of calli, somatic embryos, leaf sections, roots, or fruit sections from transformed plants were washed and cultured on recovery medium for 1–2 months, followed by subculture onto selection medium, transgenic plants were produced and the assay was repeated on the same pieces for up to 6 years posttransformation.

2.5.2 Polymerase chain reaction analysis

For molecular analysis of transformed plants the most popular method for screening large numbers of samples is polymerase chain reaction (PCR) analysis. Total genomic DNA is required to amplify the targeted gene fragments and specific primers for the targeted sequences are designed to detect the presence or absence of the transgene fragment. *Bar* and *gus* gene fragments amplified with specific primers yielded 460- and 380-bp products, respectively, for Sripaoraya *et al.* (2001). Ko *et al.* (2006), on the other hand, designed primers to amplify a 750-bp product to confirm stable *gus* transformation. They also employed specific primers designed to recognize *gfp*, *ppo* and *nptII* coding regions, giving a 710-bp fragment for the *gfp* product, a 765-bp fragment for *ppo*, and an 800-bp fragment for *nptII*.

Primers designed to amplify the region of the *bar* gene and the *nos* terminator were used by Espinosa *et al.* (2002), while internal primers for the *surB* gene were used for PCR analysis by Firoozabady *et al.* (2006) and Trusov and Botella (2006).

2.5.3 Southern blot analysis

Southern hybridization analysis confirms that the sequences between the primers are as expected and it gives an estimation of copy numbers. Differing integration patterns, as seen on the gel, verify independent transformation events and, because it is possible for several copies of transgene to insert at the same site, the copy number and the number of insertion sites are not necessarily the same.

Small amounts of genomic DNA are required for the analysis: from 5 µg (Ko *et al.*, 2006) to 8 µg (Sripaoraya *et al.*, 2001) or 10 µg (Espinosa *et al.*, 2002). In contrast, Firoozabady *et al.* (2006) digested 50 µg of DNA for hybridization.

Genomic DNA can be digested with a number of restriction enzymes. The ones reportedly used for pineapple were *SacI* (Sripaoraya *et al.*, 2001), *BamHI* (Espinosa *et al.*, 2002; Ko *et al.*, 2006 for the *gus*, *gfp* and *ppo* constructs), *HindIII* (Ko *et al.*, 2006 for the *nptII* construct), and *NcoI* (Firoozabady *et al.*, 2006).

Hybridization probes are usually specific, such as digoxigenin (DIG)-labeled *bar* and *gus* probes (Sripaoraya *et al.*, 2001), *bar* gene from the PPT-resistant plants digested with *PstI* (Espinosa *et al.*, 2002), and ³²P-labeled DNA fragments of *gus*, *gfp*, and *nptII* genes generated from PCR reactions (Ko *et al.*, 2006). However, less-specific probes have also been successfully applied, e.g., a complementary DNA (cDNA) fragment of the *Smas* promoter sequence by Firoozabady *et al.* (2006) and the CaMV 35S promoter sequence for transgenic plants carrying the *ppo* construct by Ko *et al.* (2006), thereby avoiding background detection of endogenous *ppo*.

A summary of copy numbers found in transgenic pineapple plants are listed in Table 2. Table 2 indicates that *Agrobacterium*-mediated transformation has a lower risk of integration of multiple copies, compared to the biolistics method.

Table 2 Copy numbers in transgenic pineapple lines

	Transgene	Number of copies	Reference
Agrobacterium	<i>Bar</i>	1	Espinosa <i>et al.</i> , 2002
	<i>ppo</i>	2–5	Ko <i>et al.</i> , 2005
	<i>acacs2</i>	1–6	Firoozabady <i>et al.</i> , 2006
	<i>acacs2</i>	1	Trusov and Botella, 2006
Biolistics	<i>bar</i>	4–8	Sripaoraya <i>et al.</i> , 2001
	<i>gus</i>	5–8	Ko <i>et al.</i> , 2006
	<i>gfp</i>	3–10	Ko <i>et al.</i> , 2006
	<i>ppo</i>	1–23	Ko <i>et al.</i> , 2006
	<i>nptII</i>	3–13	Ko <i>et al.</i> , 2006

2.5.4 Other analyses

An advantage of *gfp*-transformed tissue sections and shoots is that they can be monitored continuously under the stereo microscope using a filter that detects bright green fluorescence starting 4 days posttransformation treatment.

When using herbicide resistance as a selectable marker, several *in vitro* and transgene product activity assays based on herbicide resistance expression, can be performed for confirmation of stable incorporation of the transgene (Sripaoraya *et al.*, 2001, 2006a, b):

- Reverse transcriptase-PCR analysis for detection of the accumulation of *bar* transcripts, whereby total RNA was extracted from the plant and the expression of the *bar* and *gus* genes in transgenic plants was confirmed,
- Basta tolerance of regenerated micropropagated plants, by adding 0–20 mg l⁻¹ Basta (glufosinate ammonium) to the agar medium *in vitro*. After 28 days nontransformed plants were either dead on treatments above 3 mg l⁻¹ or were chlorotic/necrotic, while transformed, resistant plants had green leaves even at the highest levels of treatment,
- The same test was repeated for Basta tolerance of plants under glasshouse conditions. After acclimatization in the glasshouse for 75 days, plants were sprayed with a concentration of 100–1400 mg l⁻¹ glufosinate ammonium and scored after 14 days. All nontransformed plants died within 14 days of spraying at the 100 mg l⁻¹

rate, while PPT-tolerant plants remained green and continued to grow,

- Six-months-old glasshouse plants were planted in a field trial, where after 210 days of establishment, plants were sprayed with 0–4 g l⁻¹ glufosinate ammonium. After 28 days plants were assessed and green plants vs. chlorotic/necrotic plants regarded as an indication of survival as a result of transformed versus nontransformed status of the plants. All transgenic plants were tolerant to all herbicide concentrations evaluated, while nontransformed plants died following treatment with 2–4 g l⁻¹ glufosinate ammonium.

Firoozabady *et al.* (2006) developed a rooting assay by adding 10–100 µg l⁻¹ chlorsulfuron to the rooting medium. Transformed shoots produced roots, while nontransformed shoots did not produce roots.

2.5.5 Somaclonal variation

Plants that have been regenerated from tissue culture usually have higher rates of somaclonal variation, especially if plants were regenerated from callus tissue. Plant material used for transformation is often maintained for months, even years, under *in vitro* conditions. In addition, the stresses and cellular differentiation processes accompanying the transformation treatment can be expected to add to the *in vitro* stresses and further increase the incidence of somaclonal variation.

Leaf spininess is one of the most common variants encountered in Smooth Cayenne and the trait is relatively easy to observe and record, even at early stages of propagation. Smooth Cayenne carries the gene for spininess in a recessive form and reversion to spininess happen naturally as a result of stressed environmental conditions. Smith *et al.* (2002a) examined Smooth Cayenne plants that had been regenerated from callus cultures, those that had been micropropagated and those that had been transformed, and found that the incidence of spiny-leaved off-types were comparable. Leaf spininess varied from 0–14% for transgenic lines, 0–12% for callus lines while 11% of the micropropagated plants produced spiny leaves.

Others have encountered higher percentages of spininess in their transgenic population. Firoozabady and Moy (2004) found that plants regenerated from somatic embryo-derived cultures and from organogenic-derived cultures only had one noticeable abnormal phenotype, i.e., spininess in 21% and 4% of the plants, respectively. Whereas Firoozabady *et al.* (2006) reported 37% spininess amongst transformed plants grown in the greenhouse, which previously had been in tissue culture for 12 months. In comparison, 3–5% spininess was recorded for control micropropagated and field-propagated plants. Trusov and Botella (2006) reported 59.5% spininess in their transformed pineapple population, observed over two successive asexual generations. To determine whether the high incidences of spininess found in some of the above studies are transitory or heritable, several generations of asexual propagation are required.

Increased vegetativeness and changes in the phenotype of fruits were also observed (Smith *et al.*, 2002a) (Figure 2) and typical of changes seen in pineapples propagated directly from tissue culture derived material. Sripaoraya *et al.* (2006b) also observed increased production of slips. Many of these changes seen in the first generation of plants *ex vitro* are often not encountered in a second somatic generation derived from planting

crowns from these plants (Smith, unpublished data). This serves to reinforce the view that production of transgenic pineapples will require several cycles of selection in the field for those plants that carry the desired transgene in a stable and superior genotype.

2.5.6 Yield and quality

Reports from agronomic studies of transgenic pineapples are limited, and in many cases transgenic plants are still undergoing evaluation. Sripaoraya *et al.* (2006a, b) have evaluated their cloned transgenic field-grown plants for time to flowering, fruit size, yield, and resistance to heart and root rot diseases at time of harvest. Fruit quality, in terms of sugar and citric acid content, fiber content, aroma, and texture, have also been evaluated. They found that agronomic characteristics were not significantly different between transformed and nontransformed plants. Neither was time to flowering and fruit harvest, which was not unexpected, considering all plants were treated with ethephon to induce flowering. Aroma and texture comparisons were performed by a taste panel and transgenic plants and controls were comparable.

Similar assessments were made by O'Hare *et al.* (2003) from plants that had been engineered for blackheart resistance. They attempted to establish a correlation between variability in fruit shape in transgenic and nontransgenic fruits and its impact on organoleptic characteristics. Harvested fruits were assessed for size, shape, flesh, and skin color (hue angle), followed by removal and juicing of the pulp and a representative sample of each individual fruit measured for total soluble solids (TSS) and titratable acidity (TA). Preliminary results show that the range of fruit shapes and sizes, particularly in the first generation of plants posttissue culture, has a significant impact on both the flavor (TSS and TA) and internal flesh color. Normal-shaped fruits from different transformation events and sources had comparable TSS, TA, and internal color. In comparison, conical or bottle-shaped fruits (with "restricted necks") had significantly lower TSS and TA, which may indicate retarded fruit development. Large fruits on the other hand, had low TA but normal TSS, possibly indicating

Figure 2 Transgenic pineapple fruit; transgenic line producing normal fruit (left); variant fruit types from other transgenic lines (right); it demonstrates the need for field evaluation of each transgenic line to test for distinctness, uniformity, and stability

Figure 3 Transgenic pineapples with fruit ready for assessment

advanced maturity. Further trials are required to determine the relative stability of the observed traits in the subsequent generations (Figure 3).

Measurements of plant heights and weights of transformed versus nontransformed plants were taken by Yabor *et al.* (2006) drawing the conclusion that plant characteristics and peroxidase activity are not affected by transformation. However, this group was more interested in biochemical changes occurring in plants having undergone genetic transformation and found that levels of malondialdehyde had increased, while levels of other aldehydes, chlorophyll b, and total chlorophyll pigments within the first 30 days of establishment in the greenhouse decreased. This indicated that integration of the foreign DNA took place in the genomic region involved in synthesis of the mentioned compounds. Whether these changes affect the quality of the fruit, which is linked to public concerns regarding safety of genetically

modified (GM) food, remains to be fully examined (Sripaoraya *et al.*, 2006b).

2.6 Biosafety

A. comosus is not found naturally. It is found only under cultivation (Collins, 1960). Furthermore, Smooth Cayenne pineapple is not a competitive colonizer of natural ecosystems, and this is a stable characteristic, as evidenced by the absence of Smooth Cayenne in a natural state throughout the tropics/subtropics, where it is grown or in its center of origin in South America.

Two mechanisms of dispersal, namely, dispersal of clonally propagated plants or pollen escape need to be considered.

Pineapple is usually propagated vegetatively. All shoots produced by the plant including the crown, slips, and suckers are capable of forming a new

plant. All these vegetative structures can survive detached from the parent plant for extended periods, possibly up to 6 months depending on the prevailing conditions. In addition, the stem of the parent plant is capable of reshooting. However, while the pineapple plant is highly adapted to vegetative reproduction, it is not a likely avenue of dispersal if the site can be fenced to prevent entry of feral animals that are capable of removing fruit and slips. In addition, the *A. comosus* plant is not capable of producing underground shoots such as stolons. This is true for all the species of pineapple including the noncultivated types, with the exception of *P. saganarius*. Dispersal would, therefore, need to be by the assisted movement of vegetative parts by humans or large animals.

Cultivated pineapples can survive as volunteers in a commercial setting, where plants regrow from stem sections that are not removed when a crop is destroyed. These pose little risk in this instance as plots are usually monitored after the trials and any remaining plants destroyed by application of a suitable herbicide followed by rotary hoeing. Regulatory agencies usually require test sites to be monitored for volunteer plants for at least 2 years after the completion of the trial. If volunteers are encountered, they should be treated with herbicide or removed and destroyed by autoclaving or deep burial. No nontransformed pineapple plants should be grown at the trial site for at least 2 years following the completion of the trial.

Issues associated with the potential for pollen spread are more complex. Three scenarios, namely, cross-pollination of Smooth Cayenne pineapples, cross-pollination of other commercial types of pineapples (Queen, Mordilona, Pernambuco, Spanish groups or hybrids), and interspecific hybridization events must be considered.

Smooth Cayenne pineapples are self-incompatible and poorly fertile and autogamy is rare (Coppens d'Eeckenbrugge *et al.*, 1993). Seeds are extremely rarely seen in commercially produced Smooth Cayenne and the likelihood of transgenic pollen fertilizing Smooth Cayenne pineapples is therefore extremely low.

Hybridization of the other *A. comosus* types listed above could theoretically occur since these types are sexually compatible with Smooth Cayenne. Smooth Cayenne pineapples are also sexually compatible with the related *Ananas* species—*A. ananassoides*, *A. bracteatus*, *A. lucidus*,

A. nanus, and *A. parguazensis*. Where clones and species that are sexually compatible with Smooth Cayenne are present, it is recommended to bag transgenic flowers at test sites.

Pineapple pollen is not dispersed by wind (Kerns *et al.*, 1968). In the Americas, humming birds are considered to be the principal pollinating agents (Purseglove, 1972). Honeybees and pineapple beetles (*Nitidulid* spp.) will occasionally affect cross-pollination between different compatible cultivars if they are grown near each other (Wee and Rao, 1974). While honeybees seen visiting pineapple flowers are feeding on the nectar, which has seeped out onto the sepal and bract surfaces (Okimoto, 1948; Purseglove, 1972), they will enter the flower and collect pollen.

Pollen viability varies widely between different cultivars and species of *Ananas*. Nayar *et al.* (1981) studied seven cultivars and found viability varied from 2.5% to 55%. Smooth Cayenne's pollen viability is in the low to moderate range, however, fertility as rated by pollen quantity, viability, and seeds/flower is extremely low (Coppens d'Eeckenbrugge *et al.*, 1993).

Seed production in *A. comosus* is also very low (Coppens d'Eeckenbrugge and Duval, 1994). Moreover, there are no detailed studies on the longevity of seed survival of which we are aware. Williams (1969) reports that pineapple seed can be stored satisfactorily for one, and probably 2 years, at 10% RH and 7.2 °C. However, Miles Thomas and Holmes (1930) reported that some seeds could be viable after approximately 2.5 years. In any case, seeds are not normally found in pineapple fruits (Coppens d'Eeckenbrugge and Duval, 1994).

Since pineapple survives poorly, if at all, in the natural environment, and there seems to be no real risk associated with pollen escape, we believe pineapples are one of the safer transgenic plants to be released into the environment. However, regulators are also concerned with the transgenes and their stability of expression, whether they pose a risk to the environment, whether it is possible to identify and track the movement of transgenic plants and their parts, as well as food safety and labeling issues.

Pineapples have been transformed by both biolistics and through *Agrobacterium*-mediated methods. For biolistics transformation, vector sequences are not usually removed from the final construct. In these instances vector sequences can

integrate into the genome of transformed plants in a quasi-random fashion. For *Agrobacterium*-mediated transformation, only the recombinant transfer DNA (T-DNA) element (contained between the right and the left borders of the Ti plasmid) is transferred into plant cells.

Some components of the constructs used for transformation are derived from agents known to cause disease in plants and animals, however, none are in a form that might be considered pathogenic by themselves and most are commonly used sequences in transgenic plants. For instance, DNA segments can be derived from *E. coli*, *A. tumefaciens*, or CaMV. Therefore, even though some strains of *E. coli* are pathogenic to humans and animals, none of these segments are known to be pathogenic in the constructs used for transformation. Likewise, *A. tumefaciens* is pathogenic to plants, however, none of the sequences used in gene constructs are themselves pathogenic and while CMV is a plant pathogen and the 35S promoter is widely used in plant transformation, the sequence itself is not pathogenic.

PCR techniques have been developed for the detection of transgenic material and discussed in Section 2.5.2. One possibility for detecting GM pineapples is to use oligonucleotides that recognize the *nptII* coding region or the *bar* gene, both used as selectable marker genes. This test is highly specific and sensitive.

Transgenic phenotypes are sometimes incomplete and can behave in an unstable fashion. The aim of the field testing of transgenic lines is, therefore, to select lines with a stable predictable phenotype.

Approximately 30 mutations have been recorded in Smooth Cayenne pineapple since the early 1920s. These include white flowers (as opposed to purple), foliar floret proliferation, multiple sepals and bracts, enlarged fruit segments, protruding fruit segments, increased or decreased trichome density, seediness, multiple crowns, a lower harvest index, misshapen fruits, smaller diameter fruits, leaf spininess, reduced chlorophyll or anthocyanin levels, dwarfed characteristics, translucent fruits, multiple crowns, and fruits with increased incidence of basal knobs. Only one mutation, nonporous fruit, is considered progressive (Collins and Kerns, 1938; Groszmann, 1939). This high level of somatic mutation and high level of polymorphism within germplasm collections, as indicated by amplified fragment

length polymorphism (AFLP) markers, points to a high level of genome instability in pineapple (Kato *et al.*, 2004). Characters, such as leaf spininess, are considered extremely unstable and the frequency of mutation is high (Collins and Kerns, 1938).

Another potential source of instability is somaclonal variation, phenotypic alterations that are frequently observed in tissue culture derived plants, and this has been described in Section 2.5.5.

Because pineapple is consumed as both fresh and processed fruit, transgenic products will also fall under the scrutiny of a national food regulatory agency. In this case, data must be provided on toxicology, allergenicity, and other possible adverse effects of each transgenic line developed. In addition, nutritional quality of the food should not be adversely affected by the genetic modification. In the case of some genetic modifications, such as blackheart resistance, it is reasonable to assume that the nutritional quality will be improved. The fruit produced on plants resistant to blackheart could be left on the plant for a longer period during production in the winter months, instead of harvesting immature fruit, allowing enhanced development of sugars and other compounds normally associated with maturation of fruit. In this case, it is anticipated it may be possible to improve eating quality.

3. FUTURE ROAD MAP

3.1 Expected Products and Technologies

Transformation will undoubtedly play an important role in pineapple improvement in the not-too-distant future and could take advantage of new developments in genomics (Botella and Smith, 2008). Targeted traits for pineapple improvement through genetic engineering are: manipulation of ethylene biosynthesis to modify flowering and fruit ripening in the crop (Botella *et al.*, 2000; Firoozabady *et al.*, 2006; Trusov and Botella, 2006), suppression of the expression of the PPO gene to improve fruit quality (blackheart resistance; Graham *et al.*, 2000a; Smith *et al.*, 2002a; Ko *et al.*, 2005, 2006), pathogen resistance (nematodes; Rohrbach *et al.*, 2000; Atkinson *et al.*, 2003; suppression of mealybug populations associated with pineapple closterovirus causing pineapple wilt disease; Melzer *et al.*, 2001; *Phytophthora* fungal infection; Espinosa *et al.*,

2002), and herbicide resistance (Sripaoraya *et al.*, 2001, 2006a, b). The involvement in pineapple biotechnology of several groups around the world was discussed by Botella and Fairbairn (2005). It was indicated that although there are relatively few pineapple genes available on the public DNA databases (51 sequence entries in the GenBank nucleotide sequence database in 2004), useful genes can also be extracted from other species-independent sources. In addition, Moyle *et al.* (2005, 2006) have developed a database containing pineapple EST sequence information of genes expressed as a result of nematode-plant interaction during root infection and of genes involved in the molecular basis of nonclimacteric fruit ripening, to which pineapple belongs. This first reported collection of EST sequences isolated from pineapple contains over 5500 EST cloned sequences and aids toward understanding, isolating, and identifying genes involved in the described processes. The database can be accessed at <http://www.pgcl.com.au>.

Differences in tissue culture, regeneration and transformation efficiencies occur between pineapple cultivars and explant material. Each laboratory will employ their preferred transformation technique but should aim for reliable recovery of transgenic plants from proven, field-tested mother stock and with freedom to operate with plants and their products. More research is needed to develop an assay to screen for desired phenotypes in transgenic *in vitro* or glasshouse material, so phenotypes can be predicted prior to field planting (Wang and Waterhouse, 1997). Furthermore, as co-suppression and probably antisense constructs function at the level of messenger RNA (mRNA) degradation and involve activity of an endogenous system capable of sequence-specific degradation of mRNAs, applying these technologies to plants causes unpredictability of the nature of phenotypes which occur in individual transgenic lines. Therefore, the frequency of lines that show complete, stable gene inactivation for particular genes vary and cannot be predicted in advance (M. Graham, personal communication). In practice, this requires screening of large numbers of independent transgenic lines, involving extensive phenotypic analysis and field trials. In pineapples with cycling times of up to 22 months to produce fruit, a complete cycle of field trials will take 8–10 years. By introducing novel approaches to using new types of gene constructs, e.g., the hairpin construct as

proposed by Smith *et al.* (2000), the frequency and stability of desired phenotypes can be increased. Future assessments also require an inclusion of food-related (edible fruit quality) and environmental safety aspects of genetically modified plants (Sripaoraya *et al.*, 2006a; Yabor *et al.*, 2006).

New genes conferring important agronomic traits are still required. Among the multiple possible targets, resistance to disease and nematode attack will have the biggest effect on production. New developments in RNAi silencing are being developed to engineer durable resistance to root-knot nematodes (Huang *et al.*, 2006) and should find application in pineapple improvement. Genetic modifications leading to increased fruit nutritional quality and taste will appeal to consumers, helping to decrease the skepticism that is currently experienced towards genetically modified foods.

3.2 Addressing Risks and Concerns

A great deal of the research done on the development of transgenic pineapples has been proprietary and little has been published until recently. There are good reasons for this and much has to do with the size of the export industry and the involvement of large multinational companies in the production and marketing of the product. However, before countries will have freedom to operate with genetically engineered lines, intellectual property ownership must be ascertained and strategies put in place to ensure the plants produced are free from encumbrance, which could otherwise restrict the sale of product. Scientists and research managers need to be aware that an audit of third party intellectual property ownership is as important to their research approach as a search of the published literature. The advice of IP consultants and patent attorneys are to be valued as highly as that of scientific colleagues. A greater appreciation of the strategies that need to be put in place so that new transformed plant varieties can be grown commercially, free from any encumbrances, is mandatory for commercialization. Equally important is the need to develop and protect intellectual property.

Public acceptance is currently a major issue with all transgenic crops. The perceived safety of transgenic foods and the ownership of genetic

material are at the center of these concerns. It is difficult to anticipate changes in acceptance, but advances in transformation techniques, such as the development of selectable markers to replace antibiotic resistance markers, and the use of the technology for more consumer-orientated product improvements might improve public acceptance of GM foods. Incorporation of only native genes with expression only in plant parts not intended for consumption are also approaches worth consideration. Irrespective of changes in acceptance, it is evident that food-labeling laws in many countries will demand the identification of genetically modified contents. These laws will then require identification and segregation of fields of genetically modified plants. It is important for the pineapple industry to embrace protocols at this early stage to enable identification and segregation of genetically modified plants and thus ensure consumer confidence.

Modern tools of genomics and *trans/cis*-genics offer the possibility of completely reinventing pineapple production systems, based on the use of productive new varieties, with durable resistance to biotic and abiotic stresses. Investment is needed now to develop these improved technologies and ensure a stream of innovations that will progressively come on line to sustain the improvement in production systems. In the future, both the tools for genetic improvement and the knowledge of the ecology of pineapple production—generated in an effort to reinvent commercial production of processing pineapples—can be applied for the sustainable production of the 70% of pineapples that are currently grown for fresh fruit and local consumption around the world. These are subject to essentially the same pest and disease threats as Smooth Cayenne production but public concerns about GM and lack of information currently constrain the use of inputs or the adoption of technologies that offer sustainable increases in productivity and the development of “functional” foods (Kern, 2002).

Papaya

Dennis Gonsalves¹, Stephen A. Ferreira², Jon Y. Suzuki¹ and Savarni Tripathi¹

¹*USDA Pacific Basin Agricultural Research Center, Hilo, HI, USA, ²Department of Plant and Environmental Protection Sciences, University of Hawaii, Honolulu, HI, USA*

1. INTRODUCTION

Papaya (*Carica papaya* L.) is a large herbaceous plant native to tropical America. It is a rapidly growing, hollow stemmed, short-lived perennial of the family Caricaceae. Papaya has a long history of cultivation and use in tropical and subtropical regions between 32 degrees latitude, north and south of the equator. It is cultivated largely for consumption of fresh fruit, but in addition has several industrial, pharmaceutical, and medicinal applications. Additionally, papaya is one of only six transgenic crops that are being commercially cultivated in the United States. In 2005, the total area under transgenic crops in the United States was 49.8 hectares (James, 2005). The transgenic maize, soybean, canola, and cotton exhibit herbicide tolerance and *Bacillus thuringiensis* (*Bt*) resistance in combination or alone comprise nearly all of the transgenic acreage planted, while a very small fraction of a percentage of the biotech acreage are planted with virus-resistant transgenic squash and papaya.

This review covers the development, commercialization, and properties of transgenic papaya that have been reported in the literature. The Hawaiian transgenic papaya story is described and analyzed because it has all the elements that are needed to finally get a commercialized product, and because it represents a case in which the product was commercialized through the efforts of researchers from public institutions. All other

commercialized transgenic products have so far been commercialized by private companies. It is hoped that lessons learned in developing and commercializing transgenic papaya may serve to enhance commercial deployment of transgenic plants of other specialty crops. Several reviews have been written on the Hawaiian transgenic papaya story (Gonsalves, 1998, 2006; Gonsalves *et al.*, 1998b, 2004a, b, 2006; Fermin and Gonsalves, 2004; Fermin *et al.*, 2004b; Gonsalves and Fermin, 2004; Tripathi *et al.*, 2006; Suzuki *et al.*, 2007).

Much of the Hawaii papaya story in Section 2.1 is derived from several reviews that we have written on the subject (Gonsalves, 1998, 2006; Gonsalves *et al.*, 1998b, 2004a, b, 2006; Fermin and Gonsalves, 2004; Fermin *et al.*, 2004b; Gonsalves and Fermin, 2004; Tripathi *et al.*, 2006).

1.1 Botany of Papaya

Although its origin is not known, papaya is believed to have been domesticated in the lowlands of eastern central America, probably in the region between southern Mexico and northern Honduras (Badillo, 1971; Manshardt and Zee, 1994) by ancestors of the Maya civilization of the region (Storey, 1976; Manshardt, 1992). Following the conquest and colonial period of Spain, papaya spread rapidly along tropical trade routes. One

account suggests that papaya was taken from the Spanish Indies (West Indies) to the Malaccas and on to India and the Philippines. From the Malaccas or the Philippines, it is thought to have spread into the South Pacific Islands. The Portuguese moved papaya from Brazil to their colonies in Africa, India, and the Far East (Purseglove, 1968). By 1800, papaya was being grown throughout most of the tropical world, even in some of the most recently discovered remote islands of the South Pacific.

The Caricaceae is a small family that currently includes 6 genera and 31 species. Papaya (*C. papaya*) is the only member of the genus *Carica*. Originally, the first major monograph (Badillo, 1971) of the family Caricaceae listed 4 genera. The genus *Carica* had 22 species that were placed in two sections. Section *Carica* contained only papaya (*C. papaya*), while section *Vasconcellea* held the remaining 21 species. Two major revisions followed in 1993 and 2000 in which Badillo (2000, 2001) elevated the sections to generic level. Papaya continued to be the only member of the genus *Carica*, while the remaining 21 species were all moved to the new genus, *Vasconcellea*.

While papaya is morphologically similar to other species of the family (now recognized as species of the genus *Vasconcellea*), numerous reports indicate that papaya is genetically and reproductively isolated from the other species of the family supporting the current classification. Comparative studies of DNA species diversity utilizing amplified fragment length polymorphism (AFLP) (Kim *et al.*, 2002; Van Droogenbroeck *et al.*, 2002) and chloroplast DNA diversity utilizing restriction fragment length polymorphism (RFLP) (Aradhya *et al.*, 1999) suggest that papaya is genetically distinct from all other species of the family. Further, interspecific hybridizations have been largely unsuccessful unless tissue culture methods are used to rescue abortive embryos (Manshardt and Wenslaff, 1989a, b) thus confirming the reproductive isolation of papaya. In contrast, cross-pollination between the other species, other than papaya, is often successful, resulting in some fertile progeny (Manshardt and Wenslaff, 1989a, b; Drew *et al.*, 1998; Gonsalves *et al.*, 2006).

Papaya is a large herbaceous, dicotyledonous tree that is sparingly branched, hollow stemmed and grows up to 3–8 m in height. Plants usually produce a single erect stem with a crown of

15–20 alternate, large, palmately lobed leaves supported by smooth, hollow petioles. When grown for 4 or 5 years, trees often produce several branches.

Plants are polygamous, with male, female, and hermaphrodite flowers. Flowers are borne in leaf axils. Wild plants are frequently dioecious with female or male plant types. In contrast, domesticated plants or selections usually produce flowers that are hermaphroditic, but which can display degrees of maleness described by Storey (1941, 1976). Male or staminate flowers are long, pendulous, multiflowered cymose inflorescences. The corolla of the male flower forms a slender tube about 2/3 of its length and terminates in five free petals. The flower is unisexual, having functional stamens, but lacking a functional pistil, which is greatly reduced or vestigial. Female or pistillate flowers are inflorescences with few flowers. These flowers have large functional pistils, but are entirely lacking stamens or their vestiges. Petals are free from one another. Hermaphrodite or andromonoecious flowers are bisexual with pistil and stamens on a relatively short inflorescence. The petals are fused for one-half to three-fourths of their lengths, forming a rigid tube (Giacometti, 1987).

Papaya is a polygamous diploid with nine pairs of chromosomes and sex is determined by a single locus with multiple alleles that determines sexuality (Hofmeyr, 1967; Storey, 1976). There are two basic alleles that determine sex type. The dominant or male allele (*M*) occurs in two forms, *M_h* or *M_m*, while the female allele is recessive (*m*). Thus, staminate plants are designated *M_mm*, andro monoecious or hermaphrodite plants are designated *M_hm*, and pistillate plants are designated *mm*. An apparent lethal factor is associated with double dominant alleles (*M_hM_h*, *M_mM_m*, *M_hM_m*) since about 25% of mature seeds are aborted or empty.

The female tree is extremely stable, always producing pistillate flowers. Conversely, the staminate and hermaphrodite trees can be sensitive to fluctuations of environmental factors, and can go through seasonal sex reversals (Hofmeyr, 1939; Storey, 1941). Warm night temperatures, water stress, and high nitrogen levels can cause a sex reversal toward maleness in hermaphrodite plants (Nakasone and Paull, 1998), resulting in problems in fruit set and harvest skips during the year. These conditions often last only a few weeks, during

cooler months of the year, but contribute to less predictable yields.

Papaya fruit produced on female and hermaphrodite trees resemble melons in a superficial way. Fruit from female trees are distinctly spherical or melonlike in shape, while those from hermaphroditic trees are pyriform, oval, or cylindrical, depending on the variety. Similarly, fruit size ranges widely from 255 g to 5–6 kg. Fruit color ranges from pale to bright yellow-orange to red. Dioecious cultivars are more stable and vigorous, and grow better in the subtropical areas of Florida, Australia, and South Africa when compared to hermaphrodite cultivars, which are not adapted to cool winters (Giacometti, 1987). In most tropical countries, where production is designed for export, the Hawaiian Solo types are grown. The small fruit (450–500 g) produced by these cultivars are easier to pack and ship.

1.2 Origin of Hawaiian Solo Papaya

Little is known about the introduction of papayas into Hawaii. Some authorities credit Don Francisco de Paula Marín with bringing seeds from the Marquesas Islands to Hawaii between 1800 and 1823. Others believe that papayas came to the islands via Asia and the South Pacific islands before contact by the Europeans. Whatever its origins, it is clear the first papayas in Hawaii were the large-fruited types, typically grown in most of the papaya growing areas.

However, on October 7, 1911 Gerritt P. Wilder introduced a small-fruited papaya from Barbados to Hawaii. This introduction would completely transform the Hawaii papaya industry. These smaller papaya lines were formally named “Solo” in 1919 because Puerto Rican laborers referred to the fruit of these lines as solo, or fruits appropriately consumed by a single individual or “solo” in their language. By 1936, Solo was the only papaya variety being grown commercially in Hawaii. Subsequently, additional breeding and selection to improve the different solo varieties became the breeding objective of horticulturists at the University of Hawaii, resulting in the solo lines commonly grown in Hawaii today. The best known of these varieties are “Kapoho” and “Sunrise”, a sibling selection of Sunrise known as “Sunset” and “Waimanalo”, a deep orange-fleshed variety

prized in local markets. These solo varieties are all small-fruited varieties less than 0.65 kg in size. They are prized for their sweetness (brix levels higher than 12%), subtle nuances in flavor, and except for “Waimanalo” are firm enough to be readily handled and treated for export from Hawaii. Two of these have also become important varieties exported from Brazil, namely Sunrise and Sunset.

1.3 Economic Importance

Papaya fruit is most commonly eaten fresh, peeled, and seeded, or it is processed for making fruit salad, juice, jam, jelly, pie, or ice cream flavoring. Unripe fruit can be eaten raw in salad, cooked in syrup and eaten as a dessert, and the boiled leaves are used as vegetable. The fruit has digestive properties due to the presence of a digestive enzyme papain (Sturrock, 1940) and has nutritional value with high contents of vitamin A, vitamin C, calcium, potassium, and iron. The latex of unripe fruit is a fluid of milky appearance that contains proteinases, including papain. Papain is extracted by making incisions on the surface of green fruit, and is used to tenderize food and in pharmaceutical industries. Approximately 3501t of crude papain are exported annually from production areas (Jones and Mercier, 1974). For the majority of producer countries, papain is a by-product of fruit production (Madrigal *et al.*, 1980) from about 0.2% of the total harvested area.

Papaya is widely planted in home gardens because it is relatively easy to grow from seed. The first mature fruit can be harvested 9 months after sowing seeds, and fruit is produced year round. Commercially, when trees are grown at a density of 1500 to 2500 per hectare, annual production can range from 84 to 140 metric tons per hectare. Fruit are harvested for 1–2 years, after which the trees are usually too tall for efficient harvesting.

Papaya is now produced commercially in many of the tropical and subtropical areas of the world for both domestic consumption and for export. According to 2005 FAO statistics, the top exporting countries, in order, were: Mexico, Malaysia, Brazil, Belize, the United States (Hawaii), and the Netherlands. A significant amount of fruit is also being exported from China, India, Ecuador, Guatemala, the Philippines, France, and

Thailand. Countries with the most significant domestic production, in order, were: Brazil, Nigeria, Mexico, India, Indonesia, Ethiopia, Democratic Republic of the Congo, Peru, China, Colombia, the Philippines, Thailand, Venezuela, and Cuba.

Papaya is currently the fastest growing tropical fruit crop in the world, increasing more than 13% in 1 year (since 2004–2005). In 2005, world papaya production was estimated at 6.62 million metric tons. The two largest producers of papaya are Brazil and Nigeria with 1.7 and 0.75 million metric tons of fruit, respectively. Two largest exporters of papaya are Mexico and Malaysia with 86 260 and 44 600 metric tons of fruit, respectively. Solo type fruit produced in Hawaii and the Philippines are marketed in Japan. The major producers competing in the US market are Brazil, Mexico, Belize, and Hawaii. In the European market, Brazil is the major supplier of fruit.

1.4 Papaya Ringspot Virus

Papaya ringspot virus (PRSV) was discovered by Jensen (1949) who named the virus due to the ringspot symptoms it causes on infected fruit. It is by far the most widespread and damaging virus that infects papaya (Purcifull *et al.*, 1984). Trees infected with PRSV develop a range of symptoms: mosaic and chlorosis of leaf lamina, water-soaked oily streaks on the petiole and upper part of the trunk, and distortion of young leaves that resembles mite damage (Figure 1). Infected plants loose vigor and become stunted. When infected at the seedling stage or before flowering, trees do not normally produce mature fruit. Production of fruits by trees infected at progressively later stages is severely reduced and of poor quality, due to the presence of ringspots and lower sugar concentrations.

PRSV is a potyvirus that is transmitted in a nonpersistent manner by a number of aphid species, such as *Myzus persicae*, and has a systemic host range that is limited to papaya and cucurbits. The virus also produces local lesions on *Chenopodium quinoa* and *Chenopodium amaranticolor*. Seed transmission is not a significant means for spreading the virus, although there has been one report that described 2 of 1355 papaya seedlings from PRSV-infected fruits that

Figure 1 Symptoms of papaya ringspot virus

showed PRSV symptoms (Bayot *et al.*, 1990). As far as we know, this observation has not been confirmed. PRSV is grouped into type P (PRSV-p), which infects cucurbits and papaya, and type W (PRSV-w), which infects cucurbits but not papaya (Purcifull *et al.*, 1984). The latter type was previously referred to as watermelon mosaic virus 1 (WMV-1). Although both types are serologically closely related, observations suggest that papaya is the most important primary and secondary source for the spread of PRSV in large plantations and small orchards alike. Hereafter, we will refer to PRSV-p as PRSV.

Much progress has been made in the molecular characterization of PRSV. The positive strand genomic RNA consists of 10 326 nucleotides

and has the typical array of genes found in potyviruses (Shukla *et al.*, 1994). The genome is monocistronic and is expressed via a large polypeptide that is subsequently cleaved to yield all functional proteins. There are two possible cleavage sites, 20 amino acids apart, for the amino terminus of the coat protein (CP) (Quemada *et al.*, 1990; Yeh *et al.*, 1992). These two sites may be functional; the upstream site for producing a functional nuclear inclusion b (NIb) protein (the viral replicase), and the other, to produce the CP present in aphid-transmissible virions. It is impossible to segregate PRSV-p and PRSV-w types by their CP sequences. Within the p-types, however, the CP nucleic acid sequences can diverge by as much as 14%.

1.5 Nontransgenic Efforts to Control Papaya Ringspot Virus

Numerous efforts to identify PRSV resistance in *C. papaya* have failed, and thus control of PRSV through conventional means has been through cross-protection and the development of tolerant varieties. Resistance to PRSV has been identified in the genus *Vasconcellea* (Gonsalves *et al.*, 2006) but unfortunately crosses between *C. papaya* and *Vasconcellea* species are not fertile. However, much progress has been made in utilizing the resistance in *Vasconcellea* through initial crossing with *C. papaya* followed by embryo rescue, and subsequent backcrossing. These efforts have yet not resulted in any commercial varieties. In this section, we briefly describe the use of cross-protection and tolerant varieties that have been deployed commercially. Much information described in the sections on cross-protection and tolerant varieties were taken from reviews by one or more of the authors (Gonsalves, 1998; Gonsalves *et al.*, 2006).

1.5.1 Cross-protection

Cross-protection is the phenomenon whereby plants that are systemically infected with a mild strain of a virus are protected against the effects of infection by a more virulent-related strain (Yeh and Gonsalves, 1994). This practice has long been known and has been used to control citrus tristeza virus for many years (Costa and Muller, 1980). The

key component in cross-protection programs is the availability of a mild strain that effectively protects against the target virus. Two mild strains (Yeh and Gonsalves, 1984), designated PRSV HA 5-1 and PRSV HA 6-1, were selected following nitrous acid treatment of leaf extracts of squash infected with PRSV HA, a severe strain from Hawaii that had been recently characterized (Gonsalves and Ishii, 1980). Greenhouse experiments showed that both strains were mild on papaya and afforded protection against PRSV HA.

The mild strains were first tried in large-scale field plots in Taiwan (Wang *et al.*, 1987; Yeh *et al.*, 1988; Yeh and Gonsalves, 1994). In preliminary results, plants preinoculated with the mild strains did not show complete protection against the severe strain in the field, but did show a delay in the severe effects of the challenge virus. Although this degree of protection was insufficient for plants under severe disease pressure, economic returns could be obtained by isolating orchards as much as possible and by roguing out severely affected trees until the flowering period. About 100 to 200 hectares of papaya were protected by PRSV HA 5-1 yearly from 1985 to 1991 (Yeh and Gonsalves, 1994). The mild strains are no longer used in Taiwan because it does not provide consistent economic returns to the farmers.

The mild strains performed much better in Hawaii, presumably because the strains had been derived from a Hawaiian PRSV isolate. A series of field experiments was conducted with the Hawaiian Solo cultivars line 8, Kamiya, and Sunrise on the island of Oahu (Mau *et al.*, 1989; Ferreira *et al.*, 1992; Pitz *et al.*, 1994). These studies showed that mild strain PRSV HA 5-1 gave good protection against the local strains, although PRSV HA 5-1 produced noticeable symptoms on leaves and fruit, with the degree of symptom severity markedly dependent on the cultivar. Cultivars line 8 and Kamiya were the least affected and could be grown economically, but Sunrise was too severely affected in fruit appearance. Protection of line 8 has been the most successful (Mau *et al.*, 1989). However, cross-protection has not been widely adopted on Oahu, for several reasons: (a) the adverse affects of the mild strain on Sunrise and to a lesser extent on Kamiya, (b) cross-protection requires extra cultural management and care, and (c) the reluctance of farmers to infect their trees with a virus.

1.5.2 Tolerant varieties

Although most papayas are highly susceptible to PRSV, some selections have shown tolerance. Tolerance to PRSV is inherited in a quantitative manner (Conover and Litz, 1978) and has been incorporated into some newer cultivars by recurrent selection programs using papaya lines with moderate to high levels of tolerance crossed with local cultivars, followed by screening for resistant seedling progeny by virus inoculation. In this way, “Cariflora”, tolerant to virus found in South Florida and the Caribbean, was developed (Conover *et al.*, 1986). This selection is dioecious and produces round fruit of yellow-orange flesh. This Florida tolerant papaya does become infected by PRSV but the leaves are symptomless or show only mild mosaic phenotype and are not distorted. The fruit does not show any virus-induced distortion although fruit develop ringspots. Florida tolerant papaya produces acceptable amounts of fruit despite being infected with PRSV. However, the small round fruit and yellow flesh along with the dioeciousness are not ideal characteristics for papaya grown in tropical areas. Nevertheless, it has been used as parental genetic material for a number of breeding programs.

In Thailand, a series of papaya lines developed by crossing the Florida tolerant and local variety “Khakdum” followed by recurrent selection is the result of an ongoing breeding program since 1987 (Prasartsee *et al.*, 1998). “Khakdum” is a popular Thai cultivar with desirable fruit characteristics, but it is very susceptible to PRSV (Nopakunwong *et al.*, 1993). Plants of “Khakdum” are hermaphrodite or pistillate with the hermaphrodite producing oblong fruit of orange-red flesh. Previous trials at the Khon Kaen Horticultural Experiment Station (KKHS) (Prasartsee *et al.*, 1998) showed that Florida-tolerant papaya produced acceptable amounts of fruit despite being infected with PRSV.

Since PRSV tolerance is inherited quantitatively, a recurrent selection scheme was used to maintain tolerance and incorporate desired horticultural characteristics. Thus, only one cross was made initially between “Florida tolerant” and “Khakdum”. Subsequent crosses were made from within the progeny population. The first priority was to maintain a high level of PRSV tolerance

followed by selection of desirable horticultural characteristics. All plants were screened with a severe PRSV isolate from Thapra in Northeast Thailand. Papaya seedlings were exposed to PRSV by mechanical inoculation in the greenhouse or by aphid inoculations under field conditions where incidence of PRSV was high. Greenhouse grown and inoculated plants with mild or no symptoms were transplanted to the field for further evaluation of PRSV tolerance and horticultural characteristics.

The plants derived from seeds of papaya fruit (lines) resulting from reciprocal crosses were evaluated under field conditions. Five lines resulting from those crosses showing good PRSV tolerance were selected in the first cycle. Progeny from these promising lines were evaluated by recurrent selections through the fifth cycle resulting in the successful development of three papaya lines named “Thapra 1”, “Thapra 2”, and “Thapra 3” showing good PRSV-tolerance and horticultural characteristics.

In local field trials, the papaya cultivars “Thapra 1”, “Thapra 2”, and “Thapra 3” that showed good tolerance under heavy PRSV disease pressure at KKHS, Thapra, and Khon Kaen were subsequently tested in other areas in north-eastern, central, and southern Thailand. Data collected over 18 months from the three regional PRSV infection sites showed that “Thapra 1” and “Thapra 2” had better tolerance to virus disease under severe virus pressure compared to “Thapra 3”. “Khakdum” papaya showed the most severe symptoms under severe virus pressure. According to the results of local field trials, “Thapra 2” generally showed the most promise. Trees produced fruit as early as 3 months after transplantation into the field and the first fruit ripened at 6–7 months. The flesh of ripe fruit is light to deep yellow with a mild aroma. It is medium to large in size with long, cylindrical-shaped fruit. The average fruit weight is 1.5 kg with a Brix level of 11.2. “Thapra 2” is good for fresh consumption and desirable for canning as well. In 1997, the Department of Agriculture (DOA) released “Thapra 2” as a recommended cultivar. Its name was changed from “Thapra 2” to “Khakdum Thapra”.

Since the tolerance to PRSV found in “Khakdum Thapra” is a quantitative trait, it can be lost if that trait is not continually evaluated and selected

for in subsequent sexual generations. During large-scale production of seed, the seed source plants must have acceptable levels of tolerance and horticultural properties consistent with the line. To maintain the tolerance and qualities of the line, papaya seeds used for establishment of the plants for seed production should always be obtained from specific “Khakdum Thapra” trees identified as tolerant and having good horticultural characteristics.

Other tolerant lines have also been developed. In Taiwan, Lin *et al.* (1989) reported the development of the hybrid “Tainung No. 5”, from the cross of FL 77-5 (from Florida) and “Costa Rica Red”, with good level of tolerance and horticultural characteristics. It has a strong trunk and shows early fruit bearing and ripening. The height of the first fruit from the base of trunk is about 50–60 cm. The use of tolerant papayas has not resolved the virus problem in the long term, and elite commercial cultivars with significant tolerance have not been developed.

2. TRANSGENIC PAPAYA

Our rationale for developing PRSV-resistant transgenic papaya stemmed from the fact that PRSV was a major threat to the Hawaiian papaya industry, efforts to breed resistant cultivars were not successful, and that in the mid-1980s a major scientific breakthrough provided hope that virus-resistant transgenic plants could be developed. The latter involved the work of Beachy and colleagues (Powell-Abel *et al.*, 1986) who showed that transgenic tobacco expressing the *CP* gene of tobacco mosaic virus (TMV) provided resistance against TMV. The concept of parasite-derived resistance was brought forth at about the same time by Sanford and Johnston (1985). The concept stated that a transgenic plant that expressed a transgene of a pathogen would be resistant to that particular pathogen. Since the early reports, numerous studies have shown that “pathogen-derived resistance (PDR)” works for many plant viruses and crops. Research in the last 13 years has shown that PDR for plant viruses is RNA mediated via the mechanism of post-transcriptional gene silencing (PTGS), which is also referred to as RNA interference. It is beyond the scope of this review to delve into the details

of this mechanism, which has been covered in a number of recent reviews (Lindbo and Dougherty, 2005; Waterhouse and Fusaro, 2006).

2.1 Hawaii Papaya Story

2.1.1 Rationale for developing transgenic papaya to control PRSV in Hawaii

PRSV was first reported in Hawaii in the 1940s on Oahu Island, which at that time produced the bulk of Hawaii’s commercial papaya (Gonsalves, 1998). In the 1950s, PRSV began to severely affect papaya orchards on Oahu Island, which forced the industry to relocate. It is not entirely clear whether the original PRSV reported in the 1940s was the same virus to cause the damage, if new strains of the virus had entered Hawaii, or the original strains had mutated. Nevertheless, by the late 1950s PRSV was so severe on Oahu Island that the papaya industry was relocated to Puna on Hawaii Island. Puna is the district where Hawaii’s active volcanoes are located. Puna was a good region for papaya because of the availability of large tracts of rather inexpensive land to lease or to buy, of an abundance of rainfall (over 254 cm per year) and sunshine, of the presence of people who wanted to farm papaya, of the “Kapoho” papaya cultivar that was ideally suited for the Puna area, and importantly because of the absence of PRSV. By the 1980s, Puna was producing 95% of the state of Hawaii’s papaya, and was Hawaii’s second most important fruit crop behind pineapple.

However, the threat of PRSV to Hawaii’s papaya industry was real since the virus was present in Hilo, which was only about 31 km away. Hawaii recognized that threat and the Hawaii Department of Agriculture (HDOA) had an active program consisting of a few people that continually surveyed the Hilo area for PRSV and rogued infected trees (many of which were in people’s backyards), distributed educational material, and put a quarantine on the transport of seedlings from the Hilo area into Puna. Since it was anticipated that PRSV would eventually enter the Puna district, research was started in 1978 to develop strategies to control PRSV on Hawaii Island. Cross-protection efforts described above were investigated. However, the mild mutant, PRSV HA 5-1 was not used widely because its

effectiveness was limited to closely related isolates (Tennant *et al.*, 1994; Yeh and Gonsalves, 1994) and because it induced significant symptoms on fruit of certain papaya cultivars (Ferreira and Gonsalves, unpublished observations).

2.1.2 1985–1992: development of transgenic papaya

As noted above, Beachy's work on transgenic tobacco against TMV prompted our group, which consisted of Richard Manshardt, Jerry Slightom, and Maureen Fitch, to start work on developing transgenic papaya. The goal was to develop transgenic papaya that expressed the *CP* gene of PRSV HA 5-1, a mild nitrous acid mutant developed for cross-protection. The *CP* transgene that was engineered was actually a chimeric gene consisting of the entire *CP* gene of PRSV HA 5-1 with an additional 6 amino acids from cucumber mosaic virus because we wanted to ensure that a protein would be produced. This approach followed the prevalent hypothesis what resistance was due to the expression of the protein. As noted earlier, later evidence would show that resistance is via post-transcription gene silencing that does not require the expression of a protein. By 1987, we were starting efforts to develop transgenic papaya. Subsequent transformation and regeneration of papaya plants from embryogenic calli derived from zygotic embryos of immature papaya fruit (Fitch and Manshardt, 1990) was a major accomplishment led by Maureen Fitch. Transformation of papaya embryos with the gene gun was chosen because of the ready access to the gene gun at Cornell University at Geneva, and the help of John Sanford, a co-inventor of the technology (e.g., Sanford *et al.*, 1992). Transformation experiments resulted in the successful regeneration of nine transgenic papaya lines that were screened for resistance to PRSV HA (Fitch *et al.*, 1992). Six transformants were of the Sunset cultivar and three of the Kapoho cultivar. "Sunset" is a commercial red-fleshed Hawaiian Solo papaya that is widely grown in Brazil, but not so much in Hawaii. "Kapoho" is a yellow-fleshed Hawaiian Solo papaya that was the dominant cultivar being grown in Hawaii. By 1991, our greenhouse experiments had shown that one transgenic "Sunset" line,

Figure 2 Transgenic papaya R₀ line 55-1 (left) following greenhouse inoculation. Infected nontransgenic papaya (right), 1991

designated 55-1, was resistant to PRSV HA (Figure 2) (Fitch *et al.*, 1992).

2.1.3 1992: the merging of a research program and a disease crisis

Rather than going on the normal route of first obtaining seeds from the original, R₀ resistant line and then testing the resulting R₁ plants, we opted to directly clone the resistant R₀ line and test these clones under field conditions in a small field plot at the University of Hawaii Experiment Station on Oahu Island. This approach would turn out to be pivotal and was guided by the philosophy of the research group; basically, our primary focus was to develop a control for PRSV in Hawaii, and delving into the fine details of the mechanism of resistance was secondary.

A field trial was started in April 1992 on Oahu Island (Lius *et al.*, 1997). By December 1992, field results clearly showed that line 55-1 was resistant to PRSV in Hawaii under heavy virus pressure. By the end of 1992, nearly 100% of the nontransgenic papaya in the field trial was infected while none of the R_0 clones of line 55-1 showed symptoms (Lius *et al.*, 1997). We were convinced that line 55-1 was resistant under severe disease pressure and what remained to be seen was its horticultural suitability. Ironically, in May 1992, PRSV was discovered in Puna where 95% of Hawaii's papaya was being grown. The potential for disaster that we had contemplated over a decade before became a reality. Essentially, the challenge at hand would be to stem the spread of PRSV in Puna and commercialize line 55-1 so it could be used to control PRSV. The steps toward eventual commercialization would include testing the line for resistance, developing a suitable cultivar for the industry, on site field trial, deregulation of the transgenic papaya, obtaining licenses from holders of intellectual property that we had used to develop the transgenic papaya, and production and distribution of seeds to the industry. Furthermore, all of this work was being supported by rather small USDA special grants that had been obtained for research to improve agriculture in Hawaii and the Pacific Basin island nations for which the United States have an interest. Would we be able to overcome all of the obstacles in time to stem the impending disaster to papaya production in Hawaii?

Massive efforts to contain the virus and suppress its spread were made by the HDOA immediately after the initial sighting of the virus in Pahoia, a region of Puna. An account of the chronology of events was recently reviewed by one of us (DG) and is recaptured below (Gonsalves, 1998). HDOA immediately launched efforts to control the spread of PRSV. The area was surveyed and infected trees were rogued. By September 1992, 4915 trees had been rogued in Pahoia, and the number of trees being cut each week had decreased to below 85, providing hope that the virus had been contained (Isherwood, 1992).

However, the hope of containment was short lived. The incidence of PRSV increased dramatically in the region of Kapoho, which was closest to Pahoia, as the program of voluntary cutting of trees was not strictly followed and as farmers

experiencing high infection rates abandoned their fields, thus creating huge reservoirs of inocula that allowed aphids to quickly acquire and spread the virus (Isherwood, 1994). By late 1994, nearly all papaya of Kapoho was infected with PRSV (Figure 3). In October 1994, the HDOA declared that PRSV was uncontrollable and stopped the practice of marking trees for roguing. In less than 3 years, a third of the Puna papaya area was infected. By 1997, Pohoiki and Kahuwai were completely infected. Kalapana was the last place to become heavily infected. In this area, the furthest from the original infection site in Pahoia, the spread of PRSV was slowed by constant roguing of infected plants by farmers, who were encouraged by a small bounty paid by a packing house. Nevertheless, virus infection increased, and growers of many heavily infected orchards ceased to eliminate trees. Sixty trees had been cut in May 1996, 2905 in July, 4312 in December, and 14 493 in June 1997. By September 1997, roguing was also discontinued in Kalapana (M. Isherwood, personal communication). Five years after the onset of the virus in Pahoia, the entire Puna area was severely affected.

2.1.4 1992–1997: development and testing of “SunUp” and “Rainbow”

Line 55-1 was a red-fleshed transgenic “Sunset”, while Kapoho, the dominant cultivar in Hawaii, is yellow fleshed. We failed to obtain a virus-resistant transgenic Kapoho. Thus, our goal was to develop a papaya cultivar that would be yellow-fleshed and yet have properties similar to “Kapoho”. Richard Manshardt accomplished this in the following manner. Since line 55-1 was a hemizygous red-fleshed female, he first crossed 55-1 with a nontransgenic hermaphrodite “Sunset” to obtain F_1 seeds, and then continued a selfing program for two more generations until he had obtained plants of line 55-1 that were homozygous for resistance; i.e., all progeny from the trees were resistant to PRSV isolates from Hawaii. This homozygous 55-1 was subsequently named “UH SunUp” and is now normally referred to as “SunUp”. In its own right, this was indeed a nearly isogenic “Sunset” except that it had the transgene insert that provided resistance. To create a yellow-fleshed papaya with sufficient properties of “Kapoho” such that it

Figure 3 Severely infected papaya orchards in Puna, 1994

might be acceptable to farmers and consumers, homozygous line 55-1 (SunUp) was crossed with nontransgenic “Kapoho” and the F_1 hybrid was named “UH Rainbow” and now is commonly referred to as “Rainbow” (Manshardt, 1998). In retrospect, the decision of starting the April 1992 field trial in Waimanalo, Oahu with clones of the R_0 line 55-1 soon after greenhouse inoculations showed its resistance was very important because it allowed Manshardt to use these and subsequent plants to develop “SunUp” and “Rainbow” in a timely manner.

In October 1995, following permission granted by Animal Plant Health Inspection Service (APHIS), the field testing of Rainbow and SunUp on a farm in Puna that was severely infected with PRSV was begun. Permits were obtained by and the field trial was started under the leadership of Stephen Ferreira of the University of Hawaii at Manoa. The field trial served to validate the virus resistance of line 55-1 in both homozygous (“SunUp”) and hemizygous (“Rainbow”) conditions. It served as a site trial for farmers to observe the performance of the cultivars (which was crucial to farmer acceptance); and as a source of data on the performance of “Rainbow” grown on a solid 1 acre (0.4 hectare) planting and

managed using commercial type practices. Overall, results from the field trial seemed to validate the suitability of the cultivars for growing under Puna conditions, and importantly, it provided hope to the farmers that these cultivars might be the solution to their virus problem. Experimental data were impressive (Ferreira *et al.*, 2002). Resistance of the transgenic papaya was virtually 100% and the average yield of “Rainbow” was about 140 metric tons of marketable fruit per hectare per year, versus about 5.6 metric tons for that of control “Sunrise” papaya, all of which had become infected within 1 year of planting (Figure 4). “SunUp” also showed excellent resistance. The field trial clearly demonstrated that “Rainbow” was a viable replacement for “Kapoho”.

2.1.5 1995–1998: deregulation and commercialization of transgenic papaya

Efforts to deregulate the transgenic papaya were started in late 1995 by the same researchers that had created and tested the papaya. This section on “Deregulation and Commercialization” was taken largely from parts of a review by Gonsalves (1998).

Figure 4 Field trial of transgenic papaya in Puna. Severely infected plants (left) and noninfected transgenic Rainbow papaya (right), 1996

Transgenic plants and their products are regulated by APHIS, the Environmental Protection Agency (EPA), and the Food and Drug Administration (FDA), the latter being through a consultative process. APHIS assesses the environmental safety of the transgenic product. EPA regards the CP as a pesticide and thus an exemption had to be obtained from tolerance levels of CP in transgenic plants. The FDA assesses the food safety of the transgenic product.

APHIS was largely concerned with the potential risk of transgenic papaya on the environment. Two main risks were of heteroencapsidation of the incoming virus with CP produced by the transgenic papaya and of recombination of the transgene with incoming viruses. The former might allow non-vectored viruses to become vector transmissible, whereas the latter might result in the creation of novel viruses. A third concern—that escape of the transgenic genes to wild relatives might make the relatives more weedy or even make papaya more weedy because of resistance to PRSV was of no consequence because there are no papaya relatives

in the wild in Hawaii, nor is papaya considered a weed in Hawaii, even in areas where PRSV is not present. In November 1996, transgenic line 55-1 and its derivatives were deregulated by APHIS (Strating, 1996). This action greatly increased the efficiency of the ongoing field trial because fruit no longer had to be buried at the test site, thus allowing us to sample and send fruit to various laboratories and to the packing house for further testing.

According to the EPA, the CP transgenes are a pesticide because they confer resistance to plant viruses. A pesticide is subjected to tolerance levels in the plant. In the permit application, we petitioned for an exemption from tolerance levels of the CP produced by the transgenic plant. We contended that the CP was already present in many fruits consumed by the public, since much of the papaya eaten in the tropics is from PRSV-infected plants. In fact, we had earlier used cross-protection (the deliberate infection of papaya with a mild strain of PRSV) to control PRSV. Fruit from these trees were sold to consumers. Furthermore, there is no evidence to date that the CP of PRSV

or other plant viruses is allergenic or detrimental to human health in any way. Finally, measured amounts of CP in transgenic plants were much lower than those of infected plants. An exemption from tolerance to lines 55-1 and 63-1 was granted in August 1997.

The FDA is concerned with food safety of transgenic products. This agency follows a consultative process whereby the investigators submit an application with data and statements corroborating that the product is not harmful to human health. Several aspects of the transgenic papaya were considered: the concentration range of some important vitamins, including vitamin C; the presence of *uidA* (encoding β -glucuronidase or GUS) and *nptII* (encoding neomycin phosphotransferase) genes; and whether transgenic papaya had abnormally high concentrations of benzyl isothiocyanate. This latter compound has been reported in nontransgenic papaya (Tang, 1971). FDA approval was granted in September 1997.

In the United States, a transgenic product cannot legally be commercialized unless it is fully deregulated and until licenses are obtained for the use of the intellectual property rights for processes or components that are part of the product or that have been used to develop the product. The processes in question were the gene gun and parasite-derived resistance, in particular, CP-mediated protection. The components were translational enhancement leader sequences and genes (*nptII*, *uidA*, and *CP*). This crucial hurdle involved legal and financial considerations beyond our means and expertise. These tasks were taken up by the industry's Papaya Administrative Committee (PAC) and its legal counsel, Michael Goldman.

Several factors favored the PAC efforts to obtain licenses: (a) although the Hawaiian papaya industry is important to the state, its annual worth is relatively small (annual farm gate value of \$17 million), (b) the holders of the intellectual properties were not actively working toward developing virus-resistant transgenic papaya, (c) the transgenic papaya was urgently needed to rescue Hawaii's papaya industry, and (d) licensing the transgenic papaya in a timely manner would demonstrate goodwill in trying to help a distressed industry. Detracting from the possible success of the PAC in obtaining a license was the expense, the relatively small size of the industry, and the extra

keen public scrutiny that focuses on transgenic products. Failure by growers or shippers to follow the license agreements could be a source of embarrassment to all involved. Nevertheless, license agreements were obtained from all parties in April 1998, allowing the commercial cultivation of the papaya or its derivatives in Hawaii only. Fruits can be sold outside Hawaii, provided that the importing country allows the import and sale of transgenic papaya. Fruit derived from the licensed transgenic papaya grown outside of Hawaii cannot be sold commercially.

Even before license agreements had been obtained, the PAC had commissioned the Hawaii Agricultural Research Center to produce "Rainbow" seeds so that these would be available when the transgenic cultivars were commercialized. Free distribution of seeds sufficient for 1000 acres was started in May 1998, and farmers could now start the reclamation of abandoned and infected papaya fields by the planting of the transgenic papaya, almost exactly 6 years after PRSV was discovered in Puna.

2.1.6 1998–present: impact of the transgenic papaya

The following section points out several ways by which the transgenic papaya has impacted the Hawaiian papaya industry. The section below is largely taken from a recent review by one of us (Gonsalves, 2006). In looking at impact, it is worthwhile to note that papaya plants that become infected within several months in their growth stage will not produce saleable fruit. Thus, all the expenses for land preparation and caring for the papaya will be lost. Under these severe disease conditions, the difference between susceptible nontransgenic and resistant transgenic is a matter of fruit production versus no fruit production.

2.1.6.1 Papaya industry in 1998

The impact of the transgenic needs to be measured based on the situation of the papaya industry in 1998. As noted earlier, efforts of HDOA to contain the virus was discontinued in late 1994, people were subsequently abandoning fields and thus creating

more sources of virus, all of the Puna district was infected with only the Kalapana district having less than full infection. In Kapoho, where one third of Puna's papaya had been growing before PRSV invaded in 1992, was completely infected with many abandoned-infected fields, thus making it impossible to economically establish new papaya fields there. Moreover, much of the papaya that was sold were infected and of poor quality. The papaya production figures of Hawaii bear out the effect that PRSV was having on Hawaii's papaya industry (Gonsalves *et al.*, 2004b). Puna's papaya production had decreased from 21 800 metric tons in 1992 to 11 000 metric tons in 1998. Papaya production in Puna had fallen by 50% in a 6-year span. In 1992, Puna produced 95% of Hawaii's papaya, whereas in 1998 its share of the Hawaii's production was 75%. Other regions, primarily in the Hamakua district of Hawaii Island, on parts of Oahu Island, and on Kauai increased production and were able to pick up some of the production void left by Puna. Even with the establishing of new production areas, Hawaii's overall papaya production had slipped from 22 800 metric tons in 1992 to 14 700 metric tons in 1998.

An important impact of PRSV on the papaya industry was also on the quality of the papaya. Much of the papaya that was being harvested in Puna was infected and not of superior quality, which was the big selling point for the Hawaiian papaya. In fact, the standards of not shipping symptomatic fruit to Japan and the mainland was lifted as a measure to keep the exports of papaya to Japan and mainland at a reasonably good volume. Another impact is on the people associated with the papaya industry. In 1992, Hawaii had eight packing houses, by 1998 only three packing houses were in operation and these were not at running at full capacity as they were in 1992. It was difficult to find noninfected papaya in Hawaii.

2.1.6.2 Adoption

To capture the farmer adoption rate of the transgenic cultivars at a very early stage, a detailed survey of farmers was done from the initial seed distribution and up to September 1999 (Gonsalves *et al.*, 2004a). Personal interviews were conducted with 93 of the 171 farmers who had registered to obtain transgenic papaya seeds in 1998. The data

collected also included information on the size and types of farms, farmer attitudes, and demographic information. To the question on why they wanted to plant "Rainbow", 96% said that it was because of the ability of "Rainbow" to resist PRSV. Interestingly, 71% of the farmers had received information of the transgenic papaya through their own farmer organizations or through PAC.

Farmer adoption of the transgenic papaya was very high. Adoption was defined as to whether the farmer had planted the seeds, and not based on whether the farmer had signed up and obtained seeds. By September 1999, 90% of the farmers had obtained transgenic seeds and 76% of them had planted (adopted) the seeds. The survey also showed that farmers were ready to implement the technology; i.e., 80% of the farmers surveyed planted the seeds within 3 months of obtaining them. As noted earlier, Kapoho area of Puna succumbed to PRSV the earliest. By September 1999, 94% of the farmers in Kapoho who were surveyed had obtained transgenic papaya seeds, and 88% had planted them, and 29% had already begun to harvest fruit.

The transgenic "Rainbow" papaya is now widely planted in Puna, with many formerly abandoned fields being replanted with Rainbow. Monitoring of papaya orchards and observations by growers have clearly indicated that "Rainbow" has remained resistant to PRSV and has produced high yields of marketable fruit. In fact, papaya production increased in 1999, the first increase since 1993. Production statistics show that papaya production in Puna had increased from a low of 11 800 metric tons in 1999 to 18 100 metric tons in 2001. The percentage of transgenic papaya, as of 2005 data have varied from 40–70%, and thus it is obvious that nontransgenic papaya is still being grown in Puna. There are several reasons for this, the most important being the Japan papaya market, which will be described later.

2.1.6.3 Reversed the decrease in papaya production caused by PRSV

In 1992, when PRSV entered Puna that area produced 95% (21 800 metric tons) of Hawaii's papaya; but production decreased whereas by 1998 Puna only produced 75% (11 000 metric tons) of Hawaii's production. Papaya production in Puna

had decreased by 50% in 1998, when compared to 1992s production. Clearly, PRSV was having a devastating affect on papaya production in 1998. Production decreased slightly more in 1999, a year after seeds were released. Puna papaya production showed an increase starting in 2000 to 14 000 metric tons, 2001 with 16 000 metric tons, and 14 800 metric tons in 2002. Furthermore, Puna production accounted for 84% of the production in 2002, compared to the low of 65% in 1999. As of 2005, Puna accounted for 88% of Hawaii's papaya.

2.1.6.4 Enable the production of nontransgenic papaya in Puna

One might ask the logical question: Why does not Hawaii produce only transgenic papaya? It is critical that Hawaii continues to produce nontransgenic papaya to supply the Japan market, as will be discussed below. Arguably, one of the major contributions that the transgenic papaya has made to the papaya industry is that of helping in the economic production of nontransgenic papaya (Gonsalves and Ferreira, 2003). This has occurred in several ways. Firstly, the initial large-scale planting of transgenic papaya in established farms along with the elimination of abandoned virus-infected fields drastically reduced virus inocula. The reduction in virus inocula allowed for strategic planting of nontransgenic papaya in areas that did not have infected papaya trees. In fact, HDOA instituted a plan in 1999 to ensure the production of nontransgenic papaya in Kahuwai area of Puna. Kahuwai was isolated from established papaya fields and prevailing winds in Kahuwai came from the ocean, which borders the area (Gonsalves and Ferreira, 2003). Growers were to monitor for infection and rogue infected plants quickly. Growers who followed the recommended practices were able to economically produce "Kapoho" without major losses from PRSV. Secondly, although definitive experiments have not been carried out, it seems that transgenic papayas can provide a buffer zone to protect nontransgenic papayas that are planted within the confines of the buffer. The reasoning is that viruliferous aphids will feed on transgenic plants and thus be purged of virus before traveling to the nontransgenic plantings within the buffer. This approach also has the advantage of allowing growers to produce

transgenic and nontransgenic papaya in relatively close proximity. Timely elimination of infected trees would need to be practiced to delay large-scale infection of the nontransgenic plants.

2.1.6.5 Allow the growing of papaya in a more limited area in Puna

In the mid-1990s when PRSV was on the rampage in Puna, a number of growers moved their production to new land in the Hamakua district of Hawaii Island. This move was not disruptive to the Hamakua area because lots of agricultural land had become available in the area due to the demise of sugarcane production. With the introduction of the transgenic papaya, growers have moved back to Puna. The transgenic papaya has allowed growers to reclaim their original papaya land, and also grow nontransgenic Kapoho on land previously cultivated with papaya, so long as caution is used in establishing the stands where virus is not present. This in turn has cut down on the amount of new papaya land that has to be cleared in order to raise nontransgenic papaya for the Japan market. In other words, it has helped to slow down expansion of the industry into new lands simply to escape the virus. This situation helps environmentally by preserving forest and other lands that might otherwise be cleared for papaya plantings to escape PRSV infection.

2.1.6.6 Increase the number of papaya cultivars available to Hawaii

A common concern about genetically modified organisms (GMOs) is that they will cause a reliance on growing only transgenic crops and not encourage diversification of varieties. In fact, the transgenic papaya has had the opposite effect in Hawaii. Before 1992, nontransgenic Kapoho accounted for 95% of the state of Hawaii's production. Essentially, the papaya industry had relied on only one variety for many years. The introduction of transgenic papaya has caused the availability of new distinct varieties. While SunUp is a new variety, it essentially is a sib of Sunset and Sunrise. However, Rainbow is a new variety since it is an F₁ hybrid of a cross between nontransgenic Kapoho and SunUp. The

new transgenic cultivar “Laie Gold”, which is a hybrid between “Rainbow F₂” (selfed Rainbow) and the nontransgenic “Kamiya”, also serves a niche market on Oahu Island. Since “Rainbow F₂” is not homozygous for the *CP* gene, “Laie Gold” needs to be micropropagated to achieve uniformity of production. Micropropagation of the papaya also has the added benefit of ensuring the production of only hermaphrodite plants that is demanded by the market, of earlier and lower bearing trees with initially higher yields, and of providing selected, superior clones that could result in improved quality and yield.

2.1.6.7 *Resurgence of papaya cultivation on Oahu*

As noted earlier, the papaya industry originally was centered on Oahu, but production on that island was largely eliminated by PRSV in the 1950s. The availability of PRSV-resistant papaya provided options for papaya growers on Oahu Island. Prior to the release of transgenic papaya, Oahu growers farmed only small plots of papaya due to the effect of PRSV on production. Growers on Oahu enjoy a niche market, currently growing “Rainbow” and “Laie Gold” papaya for residents in Honolulu and other urban areas of the island. Whereas Oahu grew 20 hectares of papaya in 1960, it now grows 57 hectares of virus-resistant papaya. This would not have happened without the release and utilization of the virus-resistant transgenic papaya.

2.1.7 **Challenges of transgenic papaya in Hawaii**

Although a major constraint to papaya production in Hawaii was eliminated with the introduction of PRSV-resistant transgenic plants, Hawaii’s papaya industry still faces a number of challenges. Some of these are: gaining market share in Canada and Japan, growing of nontransgenic papaya without severe affects of PRSV, the durability of the resistance in transgenic papaya, concerns by some organic growers that their crops will be contaminated by pollen flow to their orchards, and the general controversy of GMOs. This section

has used information from a recent review by the authors (Gonsalves *et al.*, 2006).

2.1.7.1 *Supplying nontransgenic papaya to Japanese markets*

Japan and Canada are large markets for the Hawaii papaya industry. Currently, Japan accounts for 20% of Hawaii’s export market, while Canada accounts for 11%. Canada approved the import of “SunUp” and “Rainbow” transgenic papaya in January 2003, and transgenic papaya shipments are continuing to Canada. However, the application for sale of transgenic papaya in Japan has not yet been approved. Meanwhile, it is critical that papaya shipments to Japan are not contaminated with transgenic papaya fruit. Several steps are being taken to minimize contamination.

At the request of Japanese importers, HDOA adopted an Identity Preservation Protocol (IPP) that growers and shippers must adhere to in order to receive an IPP certification letter from HDOA that accompanies the papaya shipment. This is a voluntary program. Papaya shipments with this certification can be distributed in Japan without delay during the time Japanese officials are conducting spot testing to detect contaminating transgenic papaya. In contrast, papaya shipments without this certificate must remain in custody at the port of entry until Japanese officials complete their spot checks for transgenic papaya. Completing the tests may take several days or a week, during which time fruit lose quality and marketability.

Some significant features of the IPP are that the nontransgenic papaya must be harvested from papaya orchards that have been approved by HDOA (Camp III, 2003). To get approval, every tree in the proposed field must be tested for the transgenic GUS reporter gene that is linked to the virus resistance gene, and found negative. Trees (nontransgenic) must be separated by at least a 4.5 m papaya-free buffer zone, and new fields to be certified must be planted with papaya seeds that have been produced in approved non-GMO fields. Tests for detecting transgenic papaya trees in the field are monitored by HDOA and conducted by the applicant who must submit detailed records to HDOA. Before final approval of a field, HDOA

will randomly test one fruit from 1% of papaya trees in the field. If approved by HDOA, fruit from these fields can be harvested. Additionally, the applicant must submit the detailed protocols that will be followed to minimize the chance of contamination of non-GMO papaya by GMO papaya. This includes a protocol by the applicant on the random testing of papaya before they are packed for shipment. If the procedures are followed and tests are negative, a letter from HDOA will accompany the shipment stating that the shipment is in compliance with a properly conducted IPP.

The above procedure represents a good faith effort by HDOA and applicants to prevent transgenic papaya contamination in shipments of nontransgenic papaya to Japan. It also illustrates meaningful collaboration between Japan and HDOA resulting in continued shipment of nontransgenic papaya to Japan with a minimum of delay once they arrive in Japan, while adhering to the policy that transgenic papaya will not commercially enter Japan until it is deregulated by the Japanese government. These efforts, along with the effectiveness of the transgenic papaya in boosting production of nontransgenic papaya, have allowed Hawaii to maintain significant shipments of the latter to Japan.

2.1.7.2 Deregulation of transgenic papaya in Japan

Details on the efforts to deregulate the transgenic papaya are given in a recent review by the authors (Suzuki *et al.*, 2007). Obviously, deregulation of transgenic papaya in Japan will circumvent much of the concern of accidental introduction of transgenic papaya into Japan. To this end, efforts to allow the transgenic papaya into Japan were initiated by the PAC soon after the transgenic papaya was commercialized in Hawaii. Again, the researchers took the lead in developing the petition. Approval of the transgenic papaya in Japan requires the approval of the Ministry of Agriculture, Forestry, and Fisheries (MAFF) and the Ministry of Health, Labor, and Welfare (MHLW). The petition to the MAFF was approved in December 2000. The petition process for approval by MHLW is still in progress. An initial petition was submitted to MHLW in April

2003. MHLW requested more information. We are hopeful that full approval will be obtained in the near future. The transgenic papaya will need to be labeled, with the specifics of labeling being determined by the Japanese government.

The implications of receiving approval of the transgenic papaya in Japan would have huge benefits to Hawaii's papaya industry and also advance the case of transgenic products outside of the United States. Although effective, the IPP process for minimizing the introduction of transgenic papaya to Japan adds significant costs to the production of papaya. Approval will at least mean that shipment of transgenic papaya and mixed batches of nontransgenic and transgenic papaya could be shipped to Japan without fear of rejection based on having the presence of transgenic papaya.

On a broader level, because the transgenic papaya is a fresh product, consumers will have a clear, side-by-side choice. These conditions will help to answer the questions of consumer acceptance of fresh GMO products outside of the United States in a "real" and "nonacademic" case scenario. Lastly, since the product was not developed by support from multinational companies, the acceptance arguments hopefully will not be about control by large multinational companies. Instead, it is anticipated that product acceptance will be influenced by factors such as of quality, price, advertising, and philosophy of the consumer. Also the arguments should not be on major trade issues because papaya is a low-valued transgenic crop when compared to the currently approved transgenic products in countries outside of the United States. In other words, the transgenic papaya will provide us a chance to analyze factors that supposedly concern the consumers in absence of national media hype on dominance by multinational companies and so on. In this aspect, the transgenic papaya will be a ground breaking biotechnology product.

2.1.7.3 Coexistence

The conditions for deregulation of the Hawaiian transgenic papaya did not stipulate that the transgenic papaya could be grown in only certain locales or regions of the United States. However, there are concerns, especially with organic farmers

that growing of the transgenic papaya would contaminate their products and thus not make them certified or allowable for sale. The US organic rules do state that if a grower growing a product that is certified to be organic and non-GMO at the time of planting and has taken reasonable precaution against contamination, the product can be sold as organic. Nevertheless, coexistence is a contentious issue, even with the transgenic papaya. The fact that Hawaii commercially produces transgenic and nontransgenic papaya in Puna clearly shows that coexistence of transgenic and nontransgenic papaya in the same location is practical and economical. Japan has zero tolerance for having transgenic papaya being sold in Japan. Transgenic papaya has not been detected in nontransgenic shipments to Japan since the IPP program has been in place.

2.1.7.4 Durability of resistance

As will be discussed in Section 2.2.2, the resistance of Rainbow is largely limited to PRSV isolates from Hawaii, while SunUp has broader resistance due to higher dosage of the *CP* gene. However, the resistance of Rainbow in Hawaii has held up to the present time, very likely because the PRSV isolates in Hawaii are homogeneous in their *CP* sequences. The possibility of new virulent strains developing from recombination between PRSV strains in Puna with the *CP* transgene of “Rainbow” is remote. A more realistic danger is the introduction of PRSV strains from outside of Hawaii. Since SunUp should be resistant to many strains of PRSV that might be introduced into Hawaii, one would think that SunUp should be the choice for growing transgenic papaya in Hawaii. However, growers and customers prefer the yellow-fleshed papaya so it is doubtful that acreage grown with SunUp will increase significantly. Given the fact that Rainbow has narrow resistance, current practices of collecting PRSV and inoculating them to Rainbow and SunUp should continue. Since it took over 10 years to develop and commercialize the transgenic papaya, it is absolutely critical that major efforts be made to maintain the effectiveness of the Rainbow and SunUp papaya. As noted above, preventing strains of PRSV from coming into Hawaii is the most important protection.

2.1.7.5 Guarding against large scale resurgence of PRSV in nontransgenic papaya in Puna

PRSV is still in Puna, despite the fact that the transgenic papaya has served to reduce overall infection level. If virus inoculum builds up in Puna, it will become more difficult to economically produce nontransgenic papaya. Strict attention needs to be paid to planting nontransgenic papaya in as much isolation as possible, to timely elimination of infected trees, and to eliminate nontransgenic plantings that are no longer in production. Although important, these simple factors are often not practiced when there are no obvious signs for resurgence of PRSV. We cannot forget the tremendous damage that PRSV did to Hawaii’s papaya industry during the period 1992–1998.

2.1.8 Vectors and transformation protocols

2.1.8.1 Transgene engineering for PRSV resistance in papaya and methods for transformation

The PRSV-resistant transgenic papaya, Rainbow and SunUp were developed by particle bombardment with plasmid pGA482GG/cpPRV4 (Figure 5) (Ling *et al.*, 1991). The parental plasmid pGA482GG from which it was derived contains the genes *nptII* and *uidA* for the selection and visible screening, respectively of transformants as well as a multiple cloning site (MCS) within which the *CP* sequence of the attenuated derivative of Hawaii isolate HA (HA 5-1) was cloned. The PRSV HA 5-1 *CP* gene sequence was originally deciphered from a library of complementary DNAs (cDNAs) derived from purified virus particle RNA and from a partial peptide sequence of a subfragment of the purified *CP* (Quemada *et al.*, 1990). The three transgenes are flanked by transcription and termination signals recognized by the host plant (Figure 6). The *CP* gene, *nptII* and *uidA* “cassettes” are situated within T-DNA (transfer DNA) border sequences that would comprise the transgene insertion ends if in fact this vector was to be used for *Agrobacterium*-mediated transformation.

Figure 5 Transformation plasmid pGA482GG/cpPRV4. Transgene insertion borders 173 and 9955 indicate the nucleotide position endpoints of the transgene inserted in the genome of papaya line 55-1 and its derivatives. Target transgenes *nptII*, *CP*, and *uidA* encoding neomycin phosphotransferase, the *CP* gene of PRSV HA 5-1, and β -glucuronidase (GUS), respectively, as well as vector backbone genes *tetA* and *tetR*, and *aacC3* encoding tetracycline resistance and gentamycin resistance, respectively are shown as gray box arrows. Arrows indicate orientation of the respective genes. Light gray boxes represent the nonfunctional 5' and 3' halves of the β -lactamase gene (*bla5'*, *bla3'*, respectively). Replication origins are represented by open boxes and *Agrobacterium* transformation vector T-DNA left border (LB) and right border (RB) segments are represented by black boxes

As mentioned previously, the HA 5-1 *CP* transgene was also engineered to ensure translation by fusion with a 5' untranslated region (UTR) and first 16 amino acids of the cucumber mosaic virus (CMV) *CP* gene as the PRSV *CP* gene sequence is found at the end of the single PRSV-encoded polyprotein and has no translation signals of its own. Expression of the *CP* from this vector was verified by enzyme-linked immunosorbent assay (ELISA) analysis of leaves of transformed papaya and tobacco (Ling *et al.*, 1991; Tennant *et al.*, 2001). Since our original study, research by Dougherty and colleagues with

potyviruses tobacco etch virus and potato virus Y (Smith *et al.*, 1994) showed that resistance was mediated by RNA, via the mechanism of PTGS (Baulcombe, 1999, 2002). We and others have also reported evidence that PDR in transgenic papaya is mediated by RNA-based mechanisms (Tennant *et al.*, 2001; Lines *et al.*, 2002; Bau *et al.*, 2003; Davis and Ying, 2004). Indeed, reports on CP-based resistance via protein expression are largely limited to the case of TMV (Goldbach *et al.*, 2003).

In addition to the genes required for transgene function in the host plant, vector pGA482GG also contains genes *aacC3* (gentamycin-resistance gene), *tetA*, and *tetR* (tetracycline resistance genes), which contain transcription and translation signals for expression in bacteria and function in positive, antibiotic selection for the plasmid in *Escherichia coli* and *Agrobacterium*. DNA elements *oriColE1* and *oriV* are involved in plasmid replication in *E. coli* and *oriT* is involved in replication and conjugation in *E. coli* and *Agrobacterium*.

To facilitate transformation of pGA482GG/cpPRV4 for the production of SunUp and Rainbow, two parameters were considered; transformation method and tissue type to be transformed. In the initial experiments, particle gun mediated or biolistic transformation was utilized. This involved the annealing of purified transformation plasmid to tungsten particles followed by aseptic bombardment into papaya tissue prepared from either embryogenic zygotic embryos, embryogenic calli, or somatic embryos derived from hypocotyls and zygotic embryos (Fitch *et al.*, 1990, 1992; Fitch and Manshardt, 1990). It was established that (2,4-dichlorophenoxyacetic acid; 2,4-D) treated zygotic embryos derived from immature seeds of 90–120-day-old green fruits had the highest transformation capacity following particle bombardment and antibiotic selection compared to embryogenic callus (Fitch *et al.*, 1992). Subsequently, our group reported a modified transformation procedure that included the production of somatic embryos from seed-derived zygotic embryos and limiting the period of antibiotic selection, which greatly increased transformation efficiency (Gonsalves *et al.*, 1998a; Cai *et al.*, 1999). Protocols for efficient production of somatic embryos from hypocotyls and subsequent regeneration were also developed and found to be efficient for papaya transformation (Fitch *et al.*, 1993; Fitch, 1995). This had

Figure 6 Map of the functional transgene sequences of transformation plasmid pGA482GG/cpPRV4 inserted in papaya line 55-1. The functional transgenes *uidA* (encoding GUS), *CP* (encoding PRSV HA-1 CP), and *nptII* (encoding neomycin phosphotransferase) are shown labeled with black arrows denoting orientation of the genes. Triangles mark the borders of the transformation plasmid sequence insertion and papaya genomic DNA (Genomic DNA). Black boxes denote the transcription signal sequences derived from the *Cauliflower mosaic virus* (CaMV) 35S promoter (P-35S) or the nopaline synthase promoter (P-nos). Dark gray boxes denote transcription terminator sequences derived from CaMV 35S (T-35S) or nopaline synthase (T-nos). The *CP* transgene includes the leader sequence from *Cucumber mosaic virus* (CMV) and a noncoding polyA sequence as marked. Shown also are the plasmid origin of replication sequences *oriColE1* and *oriV*, the T-DNA right border sequence (T-DNA RB) and 3' region sequences of the β -lactamase gene (*bla3'*). Asterisks denote sequence truncation due to the transformation event (*) or truncation of a nonfunctional sequence (**)

the advantage that hypocotyl-derived somatic embryos are easier to procure than the zygotic embryos, which have to be individually excised from seeds of immature fruit of the correct age.

Protocols for the transformation of papaya by *Agrobacterium* have also been established and improved, providing an alternative means for production of transgenic papaya from hypocotyls, zygotic embryos, or petioles (Fitch *et al.*, 1993; Cheng *et al.*, 1996; Yang *et al.*, 1996). One potential advantage of *Agrobacterium*-mediated over biolistic-mediated transformation is that for the most part, at least in other plants, the structure of the integrated transgene DNA is predictable, consisting of the marker gene and gene of interest flanked by the *Agrobacterium* binary vector T-DNA border sequences.

Current surveys on the *CP* gene sequences from different geographic isolates of PRSV indicate that they vary as much as 14% (Jain *et al.*, 2004). This is important to consider since *CP* gene-mediated resistance breakdown has been observed when transgenic papaya was infected with PRSV isolates whose *CP* genes shared only 89.5% nucleic acid identity to the transgene *CP* (Tennant *et al.*, 2001). This phenomenon is thought to be due in part to gene silencing and the role of homology in that process. Based on these empirical observations, papaya have been transformed with a number of different *CP*s in the majority of cases obtained by use of conserved primers to the *CP* gene and polymerase chain reaction (PCR) amplification of PRSV isolates from various geographical

locations for the production of papaya lines resistant to local races of PRSV. Local papaya cultivars have often been chosen as the target of transformation to ensure that the resulting transgenic plants have the desired horticultural properties for production and consumption in the particular region. Various methods and papaya tissue types for transformation have also been adapted or modified. With regards to vector construction, the only major difference compared to the first construct pGA482GG/cpPRV4 among the various research groups is the inclusion of nontranslatable *CP* genes. Use of *CP* transgenes is the most applied approach for conferring virus resistance. However, there is one report of virus resistance conferred by the PRSV replicase (Chen *et al.*, 2001). Transgenic papayas carrying the 3'-truncated and 5'-extended replicase gene of PRSV were resistant to the local PRSV isolate and the mechanism of resistance in this case seems to be RNA mediated, but this remains to be established.

2.1.8.2 Alternative transformation procedures

Alternate transformation procedures have been addressed in a number of the transgenic papaya studies, including new antibiotic selection schemes such as hygromycin resistance, a combination of antibiotic and herbicide phosphinothricin resistance, or the avoidance of antibiotic selection

Table 1 Elements employed for the production of transgenic papaya with novel traits other than PRSV resistance and for the testing of alternative methods for selection and screening of transformants

altogether with the use of transgene encoded green fluorescent protein (GFP) for noninvasive, visual detection of transformants, or transgene conferred ability to proliferate on nonmetabolizable sugars such as mannose (Table 1).

The study using hygromycin resistance selection provided proof that this was an effective selectable marker system for transformation of papaya (Zhu *et al.*, 2004a). This is valuable information since the availability of different selectable markers can be useful in producing plants with stacked traits derived from different transgene constructs and transformation events. In addition to testing the efficacy of the hygromycin resistance marker selection system in papaya, the novel approach of co-transformation of the marker gene and gene of interest on separate plasmids was tested. Separation of the selectable marker and gene of interest opens the possibility that the marker gene could integrate at a distinct genomic site and subject to independent segregation from the gene of interest. The rate of co-transformation of the unlinked gene of interest was as high as 50% suggesting that this methodology is sufficiently efficient to make it a feasible alternate approach for obtaining transgenic papaya. In the study utilizing phosphinothricin (PPT) in the selection of papaya transformants (Cabrera-Ponce *et al.*, 1995), it is difficult to assess the efficacy of PPT and the herbicide resistance gene system, since it was used in combination with kanamycin selection.

Although antibiotic selection is a predominant method for selecting transformed plants, the antibiotic resistance genes are often the topic of contention among groups opposed to transgene technology. Antibiotic selection can be efficient in selecting transformants, but the efficiency can vary according to a number of factors including the length of the selection period, the concentration of antibiotic used, cultivar differences, and differential responses to related antibiotics such as kanamycin and G418. The development of transgenic individuals can also be slow since the antibiotic negatively selects against nontransformed cells, which is thought to cause them to produce compounds that are in general inhibitory to cell proliferation. The use of GFP has been used previously for visual screening for transformants in other plants and was shown in papaya to allow

vigorous proliferation and development of both transformed and nontransformed cells (Zhu *et al.*, 2004b). This allowed the efficient isolation and identification of papaya transformants within 3–4 weeks instead of the usual 2–3 months required in the case of antibiotic selection. A second example of the use of a nonantibiotic selection or screening system, used the phosphomannose isomerase gene (*pmi*) from *E. coli* (Zhu *et al.*, 2005). In light of concerns and perceptions on the potential negative impact of transgenes in the environment, the *PMI* gene is attractive as a transformation marker since it is widely distributed in nature. The encoded enzyme *pmi* is however lacking in many plants and is required for growth and development of papaya if sucrose that is normally used in plant tissue culture media is replaced by mannose. Mannose was shown to have inhibitory effects on growth of nontransformed papaya cells, even in the presence of sucrose. Consequently, although the selection process for transformants was long (~8 weeks), it yielded very few escapes and was in fact deemed more efficient as measured by relative numbers of transformants obtained compared to either GFP screening or *nptII* gene and G418 selection.

2.1.9 Properties of PRSV-resistant transgenic papaya

The salient properties of the virus-resistant transgenic papaya are discussed in this section. The transgenic papaya will be discussed by country or state in which they were developed.

2.1.9.1 *SunUp and Rainbow*

Line 55-1, the parent of SunUp and Rainbow, has one insert of the *CP* gene (Fitch *et al.*, 1992; Tennant *et al.*, 2001). Since the R₀ plant of line 55-1 was female, we initially obtained seeds by fertilizing the female flowers with pollen from nontransgenic “Sunset” or “Sunrise”, the parent sib from which Sunset was selected. As expected, roughly 50% of the progenies were transgenic and these would have their *CP* gene in a hemizygous state. The first extensive greenhouse tests done in 1994 clearly showed that the R₁ plants were resistant to Hawaiian strains of PRSV but largely susceptible to PRSV strains from outside

of Hawaii (Tennant *et al.*, 1994). In other words, the resistance of the line 55-1 in the hemizygous state was very narrow. For example, all R₁ plants inoculated with isolates from Thailand, Brazil, Guam, Australia, Bangladesh, India, and Taiwan were infected and developed severe symptoms while a percentage of plants that were inoculated with a strain from Mexico became infected and developed relatively milder symptoms.

In contrast, SunUp, homozygous for the *CP* gene, showed broader resistance than Rainbow, apparently due to increased *CP* gene dosage (Tennant *et al.*, 2001). It showed resistance to many but not all of the PRSV isolates from outside of Hawaii. Evidence such as effect of gene dosage, plant age, lower steady state *CP* RNA levels in SunUp than in Rainbow, and nuclear run on experiments clearly pointed to RNA-mediated protection via the mechanism of PTGS (Tennant *et al.*, 2001). Indeed, transgenic papaya expressing nontranslatable *CP* genes (Gonsalves *et al.*, 1998a) or even segments of *CP* genes showed resistance to PRSV (Gonsalves, unpublished results). Furthermore, the strength of resistance was correlated to the degree of homology of the *CP* transgene to that of the attacking virus. PRSV isolates with lesser homology are able to overcome the resistance of Rainbow and SunUp. The availability of a system to produce infectious viral transcripts of PRSV HA *in vitro* (Chiang and Yeh, 1997) provided a unique opportunity to determine the effect of *CP* homology on resistance of Rainbow and SunUp (Chiang *et al.*, 2001). An infectious PRSV HA hybrid virus containing the entire *CP* gene of PRSV YK overcame resistance of Rainbow while PRSV HA did not. PRSV YK has only 91% homology to the transgene while, as expected, PRSV HA has nearly 100% homology. PRSV HA hybrid viruses with segments of the YK *CP* gene also overcame resistance of Rainbow, but not SunUp.

2.1.9.2 Line 63-1

The original transformation work that resulted in the identification of the line 55-1, the parent of SunUp and Rainbow, also resulted in the subsequent identification of another PRSV-resistant line, designated line 63-1 (Tennant *et al.*, 2005b). In contrast to SunUp, which

was derived by transforming the nontransgenic Sunset, line 63-1 was derived by transforming the nontransgenic Sunrise and unlike line 55-1, R₀ line 63-1 was a hermaphrodite. Both Sunset and Sunrise have excellent flavor and are red flesh and were deregulated by APHIS at the same time. However, commercialization of line 63-1 was not pursued.

Interestingly, line 63-1 has at least two *CP* inserts of PRSV HA 5-1 (Souza Jr. *et al.*, 2005b; Tennant *et al.*, 2005b) that segregate independently and resistance to PRSV isolates show a clear correlation to gene dosage. As noted above, R₁ plants of line 55-1 that are hemizygous for the *CP* gene are resistant to PRSV isolates from Hawaii but susceptible to PRSV isolates from Thailand and Brazil. In contrast, only a percentage (40–60%) of R₁ plants of line 63-1 are resistant to PRSV from Hawaii, but a percentage (26–35%) of the transgenic R₁ plants also show resistance to PRSV from Thailand and Brazil (Tennant *et al.*, 2005b). Further work then showed that R₂ plants from crosses of transgenic R₁ plants were all resistant to PRSV HA, and showed variable but increased percentage of plants that were resistant to PRSV from Brazil and Thailand (Souza Jr. *et al.*, 2005b). And progeny (R₃ plants) from two self-pollinated R₂ PRSV HA-resistant plants showed 100% resistance to PRSV from Hawaii and Brazil, and averaged about 65% resistance to PRSV from Thailand. Sequence analysis showed that PRSV HA has only 89% and 92% homology to PRSV from Thailand and Brazil, respectively (Tennant *et al.*, 2001; Tripathi *et al.*, 2006). Taken together, the results with line 63-1 and also line 55-1 clearly show that gene dosage plays a major role in broadening the resistance of transgenic papaya with the PRSV HA 5-1 *CP* to PRSV isolates outside of Hawaii (Tennant *et al.*, 1994, 2001; Souza Jr. *et al.*, 2005b).

2.1.9.3 Brazil

The *CP* gene of PRSV isolate from the Southeast region of the state of Bahia was used to engineer the PRSV *CP* constructs and transform papaya via biolistic and *Agrobacterium tumefaciens*-mediated transformation. The resulting R₀ plants appeared to be resistant to the homologous virus as well

as to the Hawaiian strain PRSV HA and also an isolate from Thailand (Souza Jr., 1999; Souza Jr. *et al.*, 2005a). Candidate-resistant lines were sent to Brazil in 1999 where they were subsequently analyzed up to the third generation. The research has resulted in selection of 13 R₁ and R₂ populations that have been transferred into the papaya-breeding program at Embrapa Cassava and Tropical Fruits station in Cruz das Almas, Bahia, Brazil (Souza Jr. *et al.*, 2005a). Recently, Brazil has passed legislation to allow further testing of transgenic plants and it is hoped that more intensive work can be resumed to identify and eventually commercialize the PRSV-resistant papaya.

2.1.9.4 Jamaica

Solo type (Sunrise) papaya was successfully transformed with translatable and nontranslatable *CP* gene of PRSV (an isolate from the island of Cayman) from Jamaica by biolistic transformation (Tennant *et al.*, 2002; Fermin *et al.*, 2004b). Transgenic papaya carrying the translatable *CP* gene showed a higher (78%) resistance compared to only 10% for the transgenic plant with nontranslated *CP* gene construct. However, a delayed recovery of symptoms in subsequent new growth was observed even for the transgenic papaya that appeared to be susceptible to virus inoculation.

In 1998, initial field trial was conducted in Jamaica with R₀ plants to test the performance of transgenic papaya under natural field conditions. The field test results were similar to initial virus screening test done in greenhouse and showed 80% resistance in case of transgenic papaya carrying the translatable *CP* gene and 44% for the papaya carrying nontranslated *CP* gene. Further field tests with R₁ transgenic plants showed a similar trend to parental lines with 58% resistance (Tennant *et al.*, 2002), which indicates greater resistance was correlated to translatability of the *CP*. Further field tests have been done to characterize the resistance of the lines (Tennant *et al.*, 2005a). The characteristics (horticultural and nutrition) of transgenic papaya during the entire period of the field trial were within the range documented for nontransgenic papaya. The transgenic papaya fruits were safe for consumption as indicated by rat feeding trials conducted on transgenic

papaya fruits to test the food safety and the result showed no adverse health affects attributed solely to transgenic papaya fruit (Fermin *et al.*, 2004b).

One of the major objectives of the project was to develop the local resistant cultivars by crossing in the resistance transgene into locally favored cultivars such as large-fruited “Santa Cruz Giant” and “Cedro”, which are more preferred by the local markets in Jamaica. The Jamaican transgenic cultivars were targeted for release in 2002 initially but it has been delayed due to the lack of support for a third and final field trial. Thus, the release of transgenic papaya in Jamaica is currently on hold.

A further complication is that Europe is a significant market for Jamaican papaya, and unless the papaya is deregulated by the European Union, transgenic papaya will not be able to be exported to Europe or elsewhere. At this moment, there is still a “GMO controversy” with the deregulation of transgenic products in Europe (Fermin *et al.*, 2004b). Conceivably, this could hold back the commercialization of transgenic papaya in Jamaica for fear that the transgenic papaya from Jamaica may somehow be mistakenly shipped to Europe before it is deregulated there.

2.1.9.5 Thailand

A nontranslatable *CP* gene of a PRSV isolate from Northeast Thailand was used to engineer the two popular Thai papaya cultivars (Khakdum and Khaknun). Initially, transformants (R₀ lines) of “Khakdum” and “Khaknun” were tested for resistance in the greenhouse at the Cornell University and the selected lines were sent to Thailand in 1997 for further testing and multiplication. The performance of R₁ generation transgenic papaya under natural field conditions in 1999 was excellent. An R₃ line of “Khaknun” had been selected based on excellent PRSV resistance and horticultural characteristics in the year 2002. In comparative field trials, the transgenic papaya showed that 97% of the progeny were resistant under intense disease pressure and yielded 63 kg of fruit per tree in the first year, whereas nontransgenic papaya yielded only 0.7 kg per year. Recently, good resistance between the crosses of independent lines of Khakdum has been shown under greenhouse and field conditions

(Sakuanrungsirikul *et al.*, 2005; Gonsalves *et al.*, 2006).

A detailed characterization of properties including molecular, biological, biosafety, and food safety was initiated using material that had been selected for eventual deregulation and commercialization (Sakuanrungsirikul *et al.*, 2005). Nearly all biosafety and food-safety experiments that are mandated by the national committee on biosafety have been completed. However, the process of deregulation of transgenic papaya in Thailand will very likely slow down mainly due to recent controversial events relating to GMOs.

Recently, a group from the Mahidol University has reported the development of transgenic papaya using the CP of PRSV isolated from Ratchaburi province of Thailand (Kertbundit *et al.*, 2007). Biolistics was used to transform local papaya cultivar Khakdum. Eight lines were identified out of 1980 during kanamycin selection. Although all eight selected lines were PCR-positive for CP, only one line showed resistance following greenhouse inoculation with the homologous PRSV isolate. Further analysis of the resistant line showed a high degree of rearrangement of the inserted CP expression cassette and a deletion of 166 bp on the 3' end of the CP transgene was also observed (Kertbundit *et al.*, 2007).

2.1.9.6 Venezuela

To develop PRSV-resistant papaya, a local papaya cultivar Thailandia Roja was transformed via *A. tumefaciens* and the CP gene of a local PRSV was used as the transgene in sense/translatable, sense/untranslatable, and antisense forms (Fermin, 1996). A few putative transformed lines were recovered in 1997 and subsequently crossed. Molecular characterization of transgenic generations R₀, R₁, and R₂ and virus inoculation tests indicated that the resistance is RNA-mediated and showed a promising level of resistance not only to local isolates but also to isolates from Thailand and Hawaii (Fermin *et al.*, 2004a). A small field trial of R₁ papaya was conducted in Merida with a special permit from the Ministry of Health of Venezuela (MHV) and these transgenic papayas performed very well under local virus pressure. Unexpected problems started to emerge caused by GMO activists, during

the period that the PRSV-resistant papaya were ready to flower, and in December 2000 the field trial was set on fire by some of their members (Fermin *et al.*, 2004b). Fortunately, G. Fermin identified two hermaphrodite plants showing high level of resistance from the R₂ generation and has seeds for further multiplication and testing but their use in field trials is still in doubt.

2.1.9.7 Taiwan

PRSV-resistant transgenic papayas were successfully developed by S. D. Yeh's team at the National Chung Hsing University, Taichung (Taiwan) using the *Agrobacterium*-mediated transformation approach (Cheng *et al.*, 1996). The technology for engineering PRSV resistance was similar to that used for Hawaiian transgenic papaya. A severe local PRSV isolate (YK) was chosen instead of a mild one (as was the case for Hawaiian transgenic papaya) as a donor of the transgene (CP gene), which was transformed in local papaya cultivar, Tainung No. 2. The transformants were fully characterized and thoroughly evaluated for virus resistance. Several transformation events yielded 45 putative transgenic lines, which exhibited various levels of PRSV resistance ranging from symptom delay to complete immunity (Bau *et al.*, 2003). The mechanical inoculation studies in greenhouse with homologous PRSV showed that in addition to 16 susceptible lines with delay in symptoms expression, 17 were resistant, 10 were highly resistant, and 2 lines were immune to PRSV YK infection. Interestingly, two immune lines, 18-0-9 and 19-0-1 were not only immune to YK infection but also showed a broad-spectrum, high-level resistance to various strains of PRSV from Hawaii, Thailand, and Mexico (Bau *et al.*, 2003). Molecular characterization of nine selected lines with different levels of virus resistance has shown a negative correlation with degrees of resistance and level of transgene expression, which suggests the mechanism of resistance is RNA-mediated. Segregation studies revealed that the transgene in the immune line 18-0-9 had an inheritance of two dominant loci whereas other four highly resistant lines had single dominant loci.

Transgenic papaya lines carrying the CP gene of PRSV YK were evaluated under natural field conditions for their resistance properties and fruit

production for 4 years (1996–1999) and they performed well in regards to resistance, yield, and fruit quality. Performance of the transgenic lines in the field trials was found to be similar to that of Rainbow and SunUp in Hawaii. During field trials, none of the transgenic lines were severely infected whereas 100% of the nontransgenic plants were showing severe symptoms of PRSV infection 3–5 months after planting. However, 20–30% of transgenic plants showed mild symptoms in the first and second field trials but this did not affect the yield or fruit quality. The transgenic lines were not only protected from PRSV, but also produced 11–56% more marketable fruits compared to nontransgenic papaya (Bau *et al.*, 2004).

The CP-mediated transgenic papaya exhibited high degrees of protection against PRSV in Taiwan during a 4-year repeated field trial (Bau *et al.*, 2004). Unfortunately, 18 months after planting the fourth field trial, unexpected symptoms of severe distortion of leaves, stunting on apex, water soaking on petioles and stem, and yellow ringspot on fruit were noticed on transgenic papaya plants, which were resistant to PRSV infection during previous three field tests. Serological and biological properties of infectious agent were determined (Bau, 2000) and later identified as papaya leaf-distortion mosaic virus (PLDMV), a potyvirus, which was originally discovered in Okinawa, Japan, in 1954 (Maoka *et al.*, 1996). All transgenic papaya lines including the immune one were found susceptible to PLDMV infection when inoculated in greenhouse. Therefore, PLDMV is a potential threat to the transgenic papaya line, which is only resistant to PRSV in Taiwan.

In order to overcome the above-mentioned problem, an untranslatable chimeric construct was designed that contained the truncated PRSV CP and PLDMV CP genes and then transferred to papaya by *Agrobacterium* transformation. Transgenic papaya plants carrying these chimeric transgenes of both viruses have initially shown to have resistance in greenhouse inoculation to both PRSV and PLDMV (Yeh, unpublished results).

Transgenic papaya in Taiwan encountered another challenge at the end of fourth year of field trials, a super virulent PRSV strain 5-19 was able to breakdown the resistance in transgenic papaya lines (Tripathi *et al.*, 2004). Interestingly, the nucleotide sequence homology between the CP transgene and the CP of super strain 5-19

is less divergent than that between the CP transgene and other PRSV geographic strains such as PRSV from Hawaii, Thailand, and Mexico, which were not able to overcome the transgenic resistance (Tripathi *et al.*, 2004). This observation indicates that the sequence divergence between the infecting virus and the transgene is not the major cause of transgenic resistance breakdown. In order to analyze the role of HC-Pro as a gene-silencing suppressor, the infectious recombinant viruses were constructed by replacing an HC-Pro and CP region of PRSV YK with that of 5-19 separately or together and recombinant transcripts were inoculated on transgenic papaya (immune line) for resistance evaluation. Results showed that heterologous HC-Pro region of 5-19 alone provides the ability to breakdown the transgenic resistance even though the sequences of the transgene shares 100% sequence homology with the infecting virus (Tripathi *et al.*, 2003; Yeh *et al.*, 2005). The breakdown of the transgenic resistance by a strong gene-silencing suppressor of a super strain has strong impacts on the application of transgenic papaya for virus control in Taiwan.

2.1.9.8 Australia

The ringspot disease has not been reported to be a major limitation for papaya cultivation in Australia and the virus PRSV was described in 1991. Spread of PRSV has been restricted to only South Queensland (where the virus was first discovered) because of strict quarantine measures. However, researchers in Australia have generated transgenic papaya by biolistic transformation of local cultivars GD3-1-19 and ER6-4 that are resistant to Australian PRSV isolates. It is interesting to note that the CP nucleotide sequence data of domestic PRSV isolates have been shown to vary by only 2%. The transgene that was used for transgenic development was obtained from an isolate of Southeast Queensland and the construct was designed with a premature stop codon in the PRSV CP sequence (Lines *et al.*, 2002), thus it was expected that a functional CP would not be expressed.

The transformation event resulted in two male resistant lines for each cultivar that have multiple inserts. Molecular characterization of the transgenic plants has shown that the best resistance was exhibited by the line with the least detectable

transcript RNA, thus strongly suggesting the involvement of an RNA-silencing mechanism for viral resistance. Number of transgene copies in R_0 plants seems to play a role in the level of resistance, as those with single copies were more susceptible. This observation is consistent with that found for RNA-mediated silencing and PRSV resistance of the original Hawaiian transgenic papayas (Tennant *et al.*, 2001; Lines *et al.*, 2002).

2.1.9.9 Florida (USA)

The transgenic papaya carrying the PRSV *CP* of a Florida isolate (H1K) was developed with the intention of producing cultivars resistant to PRSV of Florida and the Caribbean region as *CP* gene sequences of Florida isolates indicate a closer relationship to PRSV sequences from Puerto Rico and Mexico. Four different types of constructs of the *CP* gene were made. The *CP* constructs (sense, antisense, frame shift, and stop-codon mutation in *CP* sequences) were transformed into immature zygotic embryos of the cultivar F65, which is an ancestor of the PRSV-tolerant cultivar Red Lady, by *Agrobacterium* (Davis and Ying, 2004). All transformants were moderate to highly resistant but none of them were immune to the homologous PRSV even when screening was done at later stages. Interestingly, the transgenic lines derived from sense and antisense constructs were infertile. The remaining lines with stop codon and frame-shift mutation were fertilized with pollen from the local cultivars Red Lady and Experimental No. 15 and cultivars grown at the University of Puerto Rico including "Puerto Rico 6-65", "Tainung No. 5", "Solo 40", and Sunrise. The "Puerto Rico 6-65" and "Tainung No. 5" are PRSV-tolerant varieties whereas "Solo 40" and Sunrise are highly sensitive. Resistance of the R_1 progeny seemed to be influenced to some extent by the particular cross, with progeny from the tolerant "Tainung No. 5" and sensitive Sunrise being more sensitive than that of other combinations.

2.1.9.10 China

The replicase gene, from PRSV was used by researchers in China to develop PRSV-resistant papaya (Chen *et al.*, 2001). For the papaya

replicase construct, the 3' end of the gene was deleted and additional codons were added to the 5' end of the gene. Embryogenic calli of papaya cultivar Tai-nong-2 were transformed by *Agrobacterium*-mediated transformation and the resulting transformants showed varying levels of resistance in response to virus inoculation in the greenhouse (Chen *et al.*, 2001). Field trials with the transgenic papaya showed protection from PRSV infection and an increase in the production of better quality papaya fruits. There was no significant difference found in nutritional quality between transgenic and nontransgenic papaya fruits (Wei *et al.*, 2005).

2.1.10 Properties of transgenic papaya regarding other traits

In addition to research directed at producing papaya resistant to PRSV, a number of groups have successfully produced transgenic papaya with properties that address a number of other causal agents of disease limiting papaya productivity worldwide. These include papaya with tolerance or resistance to fungal or oomycetes pathogens and insects, tolerance to aluminum toxicity, and herbicide tolerance aimed at relieving competition with weeds (Table 1).

Papaya is highly susceptible to root, stem, and fruit rot caused by the oomycete *Phytophthora palmivora* causing severe damage and death to trees especially in poorly drained areas during cool and rainy periods. Two studies investigated the expression of genes for defensin and Stilbene synthase, components of naturally occurring plant pathogen defense mechanisms originating from dahlia and grapevine, respectively and their efficacy against *P. palmivora* in papaya.

The dahlia defensin, DmAMP1 belongs to a group of small, structurally similar, highly basic cysteine rich peptides found ubiquitously in plants. A number of plant defensins including DmAMP1 have been shown to possess antifungal properties and expression of defensins in plants has been shown to confer resistance to certain pathogens. Similarly, ectopic expression of *DmAMP1* from the constitutive cauliflower mosaic virus promoter (CaMV 35S) in papaya was shown to confer resistance to *P. palmivora* as measured by root growth and leaf bioassays (Zhu *et al.*, 2007).

Grapevine stilbene synthase gene (*VST1*) expression in papaya was tested for its role in the production of resveratrol, a compound found in a number of, but not all plants and a member of a class of plant antipathogen compounds known as phytoalexins. It was predicted that resveratrol, could be synthesized in papaya which normally lacks it, since its substrates 4-coumaroyl-CoA and malonyl-CoA are common even in plants that do not synthesize it (Zhu *et al.*, 2004a). Since the substrates are utilized in other metabolic pathways and transgene-mediated overexpression has been shown to cause male sterility, the *VST1* gene's own promoter that induces expression temporally in response to pathogen attack, wounding or ultraviolet (UV) irradiation was utilized in the transgene construct. In papaya, *VST1* messenger-RNA (mRNA) as well resveratrol synthesis was also transiently induced in response to pathogen inoculation indicating that the signal transduction pathway activating gene expression of the grapevine transgene was also functional in the heterologous plant. Papayas expressing the *VST1* transgene were resistant to *P. palmivora* due in part to the slower growth of the pathogen on infected transgenic plants compared to their growth on nontransgenic plants.

Development of transgenic papaya resistant to insect pathogens were also developed (McCafferty *et al.*, 2006). Papayas are attacked by numerous insects that cause premature defoliation, reduced tree vigor, and fruit yield. Among these, the carmine spider mite has the largest host range and is one of the most economically important insects with regard to crop productivity. For construction of papaya resistant to the carmine spider mite, a transgene encoding chitinase from the tobacco hornworm (*Manduca sexta*) was utilized. Expression of chitinase, which degrades the polysaccharide chitin, comprising structural features of organs or cell walls of fungi, nematodes, and insects has shown promise as a biopesticide. Transgenic papayas expressing the *M. sexta* chitinase gene were indeed shown to have elevated levels of resistance to carmine spider mites as compared to wild-type controls.

Environmental stresses are also major factors leading to plant disease and several studies have attempted to find solutions to these problems using transgenic papaya. One of these is toxicity of ionized aluminum that occurs in acid soils,

which comprise 40% of arable land and is thus a major factor limiting productivity worldwide. Current practices to ameliorate this problem are through application of lime that alkalizes the soil. However, this can lead to undesirable effects on the environment due to runoff. To address this, de la Fuente *et al.* (1997) developed papaya that could grow at aluminum concentration levels six times above that which is toxic to wild-type plants via transgene conferred overexpression of citrate, an organic acid that can chelate the toxic form of aluminum. The experimental evidence from that study suggests that aluminum tolerance is conferred by excretion of the overproduced citrate from the roots of transgenic plants into the rhizosphere leading to reduced uptake of aluminum. In the study by Cabrera-Ponce *et al.* (1995) papaya plants resistant to commercially applied levels of PPT, the active component of certain herbicides, were constructed by expression of the PPT inactivating enzyme PPT acetyl transferase encoded by the *bar* gene from the bacterium *Streptomyces hygroscopicus*. Creation of herbicide-resistant lines of papaya affords the option of reducing nutrient competition from weeds through herbicide application. The above-mentioned studies indicate that transgenic papaya can be constructed to resist or be tolerant to pathogens or abiotic stresses in some cases reducing the economic and environmental costs conventionally associated with application of chemicals used to combat these problems.

There has been research initiated in the testing of transgenes to alter other properties unrelated to plant disease such as fruit ripening in papaya. This includes research toward reducing expression of endogenous papaya genes such as those encoding 1-amino cyclopropane-1-carboxylic acid (ACC) synthase (Magdalita *et al.*, 2002) or β -galactosidase (Gonsalves, unpublished data) by antisense or gene-silencing approaches, respectively. The goal of these studies is to retard the ripening process of papaya fruit by reducing production of the fruit-ripening gas ethylene, produced by ACC synthase or to retard softening of papaya fruit by reducing expression of the cell wall degrading enzyme β -galactosidase. If successful, this will demonstrate that transgene technology can be further applied to improving papaya traits involved in fruit quality.

Taken together the numerous examples of improvements in the efficiency of transformation and the varied problems they address suggest that the many tools available through transgene technology can be fully utilized and tailored for practical use in papaya.

3. FUTURE ROAD MAP

3.1 Some Potential Products

The future impact of transgenic papaya for worldwide PRSV control and for contributing in a number of other areas is bright technically for several reasons. The demonstrated resistance to PRSV by transgenic papaya has remained highly effective for nearly a decade. Other countries have developed transgenic papayas that show resistance to strains of PRSV in their countries. A major development is that the genome of SunUp papaya is close to being sequenced (M. Alam, personal communication). This achievement will open up the avenue to a multitude of potentials for various products to come from papaya and also for developing new transgenic products. Some products that come to mind are transgenic papaya with delayed ripening or softening of fruit to help in long distance transport of papaya, developing papaya that are only hermaphrodite by knowing the specific genes that govern the sex of papaya, development of lines of papaya that have increased levels of papain, and development of transgenic papaya with resistance to other important pests and diseases of papaya, such as black spot of fruit and phytophthora blight of papaya. Since transformation of papaya via biolistics (particle bombardment) or *Agrobacterium* is efficient, the development of papaya with the target traits is very doable. The largest challenge will be the regulatory issues, intellectual property issues, and the fact that papaya is not a commodity crop.

3.2 Challenges

Currently, the major obstacles for realizing the potentials of transgenic papaya with various properties rests in the regulatory issues and in whether public institutions will have the interest in pursuing transgenic papaya as a research area

given the fact that it is not a commodity, and is not likely to be developed by private companies. The Hawaiian transgenic papaya story is a testament that a transgenic crop can be developed and commercialized through the efforts of public institutions. However, the transgenic papaya is the only product that has been commercialized by a public institution and this was done nearly a decade ago.

Risks or perception of risks of transgenic crops are not unique to any one crop. Potential barriers to the further development of transgenic crops is more related to the time and money that it takes to do the research and come up with the data that the regulatory agencies need to make a judgment on the safety of the product from the food and environmental standpoint. It is logical to think that private companies will focus on products for which they can expect a reasonable profit and thus it is not surprising that efforts have been focused on commercializing crops such as canola, corn, soybean, and cotton. Papaya is but a tiny fraction of the value of these crops. In summary, practical deployment of the papaya will fall largely to the tasks of public institutions, unless some yet unseen extremely valuable product can be developed from papaya. Nevertheless, the Hawaii papaya story clearly shows that transgenic papaya can be developed by public institutions and be done in a timely manner and have impact. It will be indeed interesting to see if other transgenic papaya will be commercialized in the fairly near future.

Mango

Richard E. Litz

Tropical Research and Education Center, University of Florida, Homestead, FL, USA

1. INTRODUCTION

1.1 History, Origin, and Distribution

Mango, *Mangifera indica* L., cultivation probably originated in India 4000 years ago (DeCandolle, 1884). At that time, mango trees most likely produced small fruit with a thin flesh, and domestication over many centuries resulted in larger fruit with thick flesh. According to Mukherjee (1950) many of these primitive mangoes still occur in Northeastern India; with considerable variation in fruit shape and size. The mango has remained an important religious and cultural symbol for India. Gautama Buddha was presented a mango grove by Amradarika (ca. 500 BC) as a quiet meditation place (Popenoe, 1932). The Indian subcontinent was the birthplace of some of the earliest highly developed civilizations, and India exerted strong cultural, religious, and commercial influence over South and Southeast Asia. Hinduism, Buddhism, and Islam were all introduced into Southeast Asia from India. The word for mango in Malaysia and Java (Indonesia) is “mangga”, which is derived from the Tamil “manga”. Although superior Indian mango selections may have been introduced into Southeast Asia, there is little evidence today and the most important mango selections of Southeast Asia are all of the polyembryonic type, and have traditionally been seed propagated.

It is believed that the Portuguese introduced methods for vegetative propagation into India in

the late 15th century. During the reign of the emperor Akbar (1556–1605), the “Lakh Bagh”, a mango orchard of 100 000 trees, was established in Bihar. Many of the mango cultivars of India originated from selections from the Lakh Bagh, for example, “Alphonso”, “Dashehari”, “Langra”, “Rani Pasand”, “Safdar Pasand”, etc. Mukherjee *et al.* (1983) indicated that remnants of this and other ancient orchards still exist in India, and might provide valuable material for breeding.

Although the center of origin and diversity of the genus *Mangifera* is in Southeast Asia, the origin of *M. indica* is less clear. According to Mukherjee (1951), *M. indica* might have appeared during the Quaternary period. It was once believed that mango must have originated in India and spread from there to Southeast Asia, the New World, and Africa. Northeastern India is at the northern edge of the distribution of *Mangifera* species, and mango might have been first naturalized in India (Hooker, 1876). Taxonomic and molecular evidence indicate that the mango evolved within an area encompassing Northwestern Myanmar, Bangladesh, and Northeastern India.

The spread of mangos beyond South and Southeast Asia probably did not occur before the beginning of the European voyages of the 15th and 16th centuries. Mango seeds are recalcitrant, and mango germplasm in the early days must have been transported as ripe fruit and/or seedlings. Only after the 15th and 16th centuries could grafted plants be transported for long distances. The Portuguese would have

transported the mango from India to their African colonies of Mozambique and Angola; however, there is a possibility that mango was introduced to Africa via Arabia in the 10th century by Omani traders (Purseglove, 1972). From Mozambique and Angola, the mango would have been introduced into Brazil. The Spaniards introduced polyembryonic mango types to their New World colonies through the Pacific trading ports of Acapulco and Panama City. Polyembryonic “Manila” is the most important mango cultivar of Mexico, and is considered to be identical to the Philippine polyembryonic “Carabao”. The mangoes in the West Indies are derived from introductions from Brazil during the mid- to late-18th century. The “No. 11”, a polyembryonic mango seedling from Cuba, was the first introduction into Florida (USA) in 1861. Another polyembryonic selection, “Peach”, was introduced into Florida a few years later (Knight and Schnell, 1993). Except for “Mulgoba” (sic.), the early introductions into Florida were unproductive, and only “Mulgoba” was ever grown commercially.

1.2 Botanical Description

The mango, *M. indica* L., is in the Anacardiaceae family in the order Sapindales. The Anacardiaceae consists primarily of tropical species. In addition to the mango, other important species include the cashew *Anacardium occidentale* L., pistachio *Pistacia vera* L., the mombins *Spondias mombin* L. and *Spondias purpurea* L., and the ambarella *Spondias dulcis* Forst. The family also contains the poison ivies and oaks (*Rhus* spp.) of North America and the rengas (*Gluta* spp.) of Southeast Asia. Some of the *Mangifera* species also produce resinous sap that can induce allergic reactions.

Most *Mangifera* species occur naturally in the Malay Peninsula, the Indonesian archipelago, Thailand, Indochina, and the Philippines (Mukherjee, 1985; Bompard, 1989). Kostermans and Bompard (1993) classified *Mangifera* species based upon floral morphology and identified 69 species in two subgenera *Mangifera* and *Limus* with 11 additional species of uncertain position. Eiadthong *et al.* (1999) used genomic restriction fragment length polymorphism (RFLP) and amplification of chloroplast DNA (cpDNA)

to describe phylogenetic relationships among *Mangifera* species. Molecular biology will probably have a major impact on phylogenetic studies of mango and its relatives.

Mangifera species having a single fertile stamen occur in Northeastern India, Myanmar, Thailand, and the Malay Peninsula. Many *Mangifera* species have small fruits with thin, acidic flesh, large seeds, abundant fiber, and astringent resinous substances close to the skin. Edible fruit is produced by *M. indica* and 26 other species in the genus, primarily those from Southeast Asia (Gruezo, 1992). *Mangifera foetida* fruit are highly astringent, and are used for pickles and as a tamarind substitute (Bompard, 1992b). *Mangifera kemang* and *Mangifera altissima* are consumed as fresh fruit or in salads (Angeles, 1992; Bompard, 1992a). *Mangifera caesia* is cultivated in Java (Bompard, 1992a). *Mangifera pajang* produces large and attractive fruit. *Mangifera odorata* is grown in the humid lowlands of Southeast Asia in areas that are otherwise unsuitable for mango, and can also be utilized as a rootstock for mango (Ochse, 1931; Bompard, 1992c). *Mangifera laurina* and *Mangifera pentandra* are used in salads (Bompard, 1992d). *Mangifera griffithii*, *Mangifera minor*, *Mangifera monandra*, *Mangifera quadrifida*, and *Mangifera similis* are considered to have potential as fresh fruit (Gruezo, 1992). The common mango *M. indica* includes all of the commercial cultivars.

There are two distinct types within *M. indica* based upon their reproduction systems and their centers of diversity: a subtropical group with monoembryonic seed (Indian type) and a tropical group with polyembryonic seed (Southeast Asian). Although a few polyembryonic cultivars do occur along the west coast of India, they probably were introduced from Southeast Asia into Goa by the Portuguese. This is supported by a study of relatedness among polyembryonic and monoembryonic cultivars from the west coast of southern India using genomic and cpDNA RFLP analysis (Kumar *et al.*, 2001), and the conclusion was that polyembryonic mangoes could not have originated in India, and must have been introduced from Southeast Asia.

There have been very few genetic studies involving mango. The chromosome numbers of *M. caesia*, *Mangifera caloneura*, *M. foetida*, *M. indica*, *Mangifera sylvatica*, *M. odorata* and *Mangifera*

zeylanica have all been reported to be $2n = 2x = 40$ and $n = 20$ (Mukherjee, 1950, 1957; Roy and Visweswariya, 1951). The mango is believed to be an allopolyploid (Mukherjee, 1950). Because of the presence of secondary associations that occur during metaphase of meiosis, Mukherjee (1950) suggested that the basic chromosome number was $n = 8$. He also noted that the high number of somatic and nucleolar chromosomes supported this conclusion; however, this has not been confirmed by other researchers. Arumuganathan and Earle (1991) determined that the nuclear DNA content of mango is approximately 0.91 pg (picogram).

Traditional breeding has had relatively little impact on mango cultivar release. This is due to several factors: the long juvenile period of the species, which is approximately 7 years; the long period required for assessing the productivity of seedling trees, which can be 12–13 years; the relatively low success rate of controlled hand pollinations, which varies from 0.23% to 3.85% (Mukherjee *et al.*, 1968; Singh *et al.*, 1980); and consumer resistance to change in the traditional mango-growing cultures. Consequently, virtually all cultivars have been derived from seedlings of open-pollinated trees.

During the 20th century, several new mango cultivars were identified in Florida, USA. A seedling of open-pollinated “Mulgoba” came into production in Florida in 1910. The fruit had a red blush, and the tree was more productive than its parent (Wolfe, 1962). The selection was named “Haden”. Another early selection was “Brooks”, which is a seedling of “Sandersha”. During the 20th century, introductions of mango germplasm into Florida occurred from Southeast Asia, India, and elsewhere. Prior to the use of molecular genetics for genetic diversity analyses and pedigree inferences, it was thought that these introductions constituted a secondary center of mango genetic diversity (Knight and Schnell, 1993; Schnell *et al.*, 1995; Mukherjee, 1997). However, it is now considered that all Florida mango cultivars are derived from as few as four monoembryonic Indian cultivars and a single polyembryonic landrace “Turpentine” (Schnell *et al.*, 2006). The second generation “Haden” progeny include “Cushman”, “Edward”, “Lippens”, “Florigon”, “Palmer”, “Springfels”, and “Van Dyke”; “Keitt” and “Kent” were selected from “Brooks” seedlings.

The next generation of Florida cultivars that were seedlings of “Haden” included “Cogshall”, “Earlygold”, “Glenn”, “Hodson”, “Irwin”, “Ruby”, and “Valencia Pride”; whereas, “Sensation” was selected from a “Brooks” seedling. Florida cultivars are suited for many agroecological areas and bear regularly, although many Indian cultivars have been unproductive outside their center of domestication, and are alternate bearing. Florida cultivars also have a red blush at maturity, firm flesh, a high flesh to seed ratio, and are regular bearing. The attractive red blush is favored by consumers in nontraditional mango-consuming countries (Knight, 1997). “Tommy Atkins”, “Keitt”, etc. are moderately resistant to anthracnose, which is the most important production and postharvest problem in many areas. In the latter half of the 20th century, plantings of Florida cultivars were established in many countries and form the basis of international trade of mango fruit.

1.3 Economic Importance

Mangoes are grown commercially throughout the tropics and also in many subtropical areas. It is the most important fruit crop of Asia, and ranks fifth worldwide in total production (metric tons) among fruit crops, after *Musa* (105 815 354), *Citrus* (105 440 168), grapes (65 584 233), and apples (59 444 377) (FAOSTAT, 2006). According to FAOSTAT (2006), world mango production has increased by 67% between 1990 and 2005, with production of approximately 28 221 510 metric tons in 2005. India produced approximately 51% of the world’s mangoes in 1990, but India’s share had declined to approximately 38% by 2005. The leading producing nations after India are (in metric tons) China (3 450 000), Thailand (1 800 000), Pakistan (1 673 900), Mexico (1 600 000), Indonesia (1 478 204), Brazil (1 000 000), and the Philippines (950 000). Between 1990 and 2005, mango exports increased sixfold from 158 030 to 907 782 metric tons, with a value estimated to be US\$583 763 000 (FAOSTAT, 2006). Major exporting countries are (in metric tons) Mexico (212 505), India (156 222), and Brazil (111 181).

Mangoes represent an important part of the diet in many less developed countries of the subtropics and tropics. Their attractiveness and flavor have

also enhanced the quality of life in these countries. Approximately 1% of mango production is utilized for processing for juice, nectars, preserves (including chutney), fruit leather, frozen pulp, and for flavoring baked goods, ice cream, yoghurt, etc. (Nanjundaswamy, 1997; Raymundo *et al.*, 2008). The seed is the source of the starch “amchur”, and anacardic acid is extracted from the skin. The timber of mango trees is of low quality, and the tree bark is an important source of tannins for curing leather.

1.4 Traditional Breeding: Breeding Objectives, Tools, Strategies, and Achievements

Almost all of the mango cultivars are derived from open-pollinated seedlings (see above). Nonetheless, several horticultural traits involving fruit quality and tree architecture have been targeted for improvement (Iyer and Degani, 1997). (1) Regularity of bearing, particularly in biennial bearing Indian-type mangoes, is a high priority. (2) Shortening the juvenile period to enable early flowering and bearing, i.e., precocity, would bring new orchards into earlier production. (3) A compact or dwarf habit would allow high density planting. (4) Resistance to a number of pests and diseases is very important. Diseases that affect mango production and postharvest include anthracnose, which is caused by *Colletotrichum gloeosporioides* (Penz) Penz & Sacc. in Penz and *Alternaria* rot, which is caused by *Alternaria alternata* (FR.:FR.) Keissel (Dodd *et al.*, 1997; Ploetz and Prakash, 1997). (5) The mango fruit should have skin that has an attractive blush, pleasant taste, and aroma and the pulp should be fibreless. (6) Mango fruit is an important export commodity, and therefore extended shelf life and freedom from physiological disorders that cause precocious fruit ripening, for example, “jelly seed” and “soft nose”, in certain important export cultivars, such as ‘Tommy Atkins’, are important.

Mango cultivars that have emerged from breeding programs and which involved controlled pollinations include the successful “Swarnajehangir”, “Mallika” (“Neelum” × “Dashehari”), and “Amrapalli” (“Dashehari” × “Neelum”) in India (Iyer and Degani, 1998). In Australia, “Calypso” has been rapidly adopted by the mango industry (Iyer and Schnell, 2008).

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

Conventional breeding has not had much impact on mango cultivar development, and almost all cultivars are selections made among seedlings of open-pollinated trees. It is difficult to make controlled crosses between selected mango trees because of the low frequency of fruit set (<0.01%) (Iyer and Degani, 1997) and the universal occurrence of polyembryony in Southeast Asian mangoes. *M. indica* is extremely heterogeneous due to extensive outcrossing and polyploidy ($2n = 4x = 40$) (Mukherjee, 1950). The long juvenile period, which can be at least 7 years following germination, and the time required for evaluation of the mature tree, i.e., 12–15 years after germination, have also impeded breeding. Cultivars that have been released from contemporary breeding programs for the most part have not been accepted in traditional mango producing countries of South and Southeast Asia, because their fruit quality has generally been considered to be inferior to traditional selections.

Because of the problems associated with conventional breeding of mango, genetic transformation holds promise that existing superior cultivars can be transformed with a gene that mediates an important horticultural trait. Fully ripened mango fruit are highly perishable, largely due to the rapid development of anthracnose. Significant changes occur during fruit ripening that affect texture, and these changes can affect fruit storage. Consequently, mango fruits are usually harvested before maturity, when they cannot ripen normally and their flavor is not fully developed (Medlicott *et al.*, 1988). Postharvest losses in storage and in transit to markets can range from 10% to 80% (Gómez Lim and Litz, 2007). Mango fruit physiology resembles other temperate and subtropical climacteric fruit. The differences with respect to temperate fruit involve major substrates during ripening, the rate of ripening and senescence, the order in which the components of ripening occur and chilling sensitivity (Gómez Lim and Litz, 2007).

Softening of fruit occurs as a result of hydrolysis of different cell wall components, solubilization of pectin (Roe and Bruemmer, 1981; Lazan *et al.*, 1986) and a net loss of arabinose, galactose, and galacturonic acid (Brinson *et al.*, 1988).

Various cell wall hydrolytic enzymes increase in activity during softening (Gómez Lim, 1997a). Mature green mango fruit contains accumulated starch (Subramanyam *et al.*, 1976), which is hydrolyzed during ripening (Morga *et al.*, 1979), resulting in increased total sugars, primarily the monosaccharides glucose and fructose (Selvaraj *et al.*, 1989) and sucrose (Castrillo *et al.*, 1992). The total sugar content varies among cultivars, for example, “Carabao” has one of the highest values (Peacock and Brown, 1984), whereas “Golek” has one of the lowest (Lizada, 1993). The activities of both amylase and sucrose phosphate synthase increase several fold during ripening (Mattoo *et al.*, 1975; Castrillo *et al.*, 1992).

Mango fruits are climacteric with a moderate respiration rate (Kader *et al.*, 1985), since there appears to be a relationship between respiration rate and storage life, reducing respiration should increase postharvest life. With many fruits, the respiration rate can be controlled by temperature management; however, tropical fruits are sensitive to low temperature. Climacteric fruits demonstrate increased ethylene production during ripening, and fruits of different species appear to have different sensitivities to ethylene. The climacteric and the ethylene peak in mango occur simultaneously (Tucker and Grierson, 1987).

Ethylene biosynthesis is mediated by enzymes that catalyze the conversion of S-adenosylmethionine (SAM) to 1-aminocyclopropane-1-carboxylic acid (ACC) and ACC to ethylene, i.e., ACC synthase and ACC oxidase or ethylene forming enzyme (EFE) (Adams and Yang, 1979; Kende, 1993). Burg and Burg (1962) observed a small peak of ethylene during ripening of monoembryonic “Haden” and “Kent”, and this has been confirmed with polyembryonic “Carabao” (Cua and Lizada, 1990) and “Manila” (López-Gómez and Gómez Lim, 1992). Ethylene production increases considerably during the climacteric. “Carabao” mangoes produce ethylene prior to full maturity with the highest rate occurring in the outer mesocarp (Cua and Lizada, 1990). The levels of ACC are similar throughout the mesocarp.

Premature ripening of mango fruit has been a cause of large-scale postharvest spoilage. The current strategies that have been adopted to prevent or reduce this spoilage include harvesting of mature green fruit, exposure of fruit to ethylene adsorbents, including potassium permanganate or activated charcoal/vanadium oxide (Maekawa,

1990) and storage of fruit at optimum temperature. Ripening of mango fruit can be delayed when preclimacteric fruits are treated with 1-methylcyclopropane (Jiang and Joyce, 2000; de Silva *et al.*, 2004; dos Santos *et al.*, 2004). Storage temperature is dependent upon cultivar, preharvest environment (Arpaia, 1993), maturity at harvest (Kader *et al.*, 1985), and storage conditions (Kader, 1994). Storage at temperatures above 8–12 °C causes ripening and senescence, and lower temperatures cause chilling injury.

Mango fruits have poor storage quality, and storage in modified atmospheres causes physiological disorders (Chaplin, 1989), which can affect skin, flesh, and other ripening attributes. Chilling injuries include pitting, darkening, uneven ripening, and susceptibility to decay. Storage life and sensitivity to chilling injury depend on fruit maturity and storage temperature. Fruit harvested at early stages of maturation ripen slowly and are more susceptible to chilling injury (Kader, 1994). Ripe fruits are less susceptible to chilling injury (Medlicott *et al.*, 1990a, b) and can be stored for up to 21 days at <8 °C without deterioration in quality, although fruits may deteriorate rapidly after removal from storage (Johnson *et al.*, 1997).

Storage of mango fruit in modified atmospheres has not been particularly successful, and fruit develop poor color, eating quality, and undesirable flavors. Mango ripening has never been delayed satisfactorily in this way (Chaplin, 1989), although Kader (1994) suggested some modified atmospheres for storage of mango could delay ripening with increased firmness retention.

2. DEVELOPMENT OF TRANSGENIC MANGOES

Premature, ethylene-induced fruit ripening lowers the yield of mango. Because this occurs before shipping or in transit to markets, mango fruits are highly perishable and have a short shelf life. Postharvest problems of many temperate fruits have been addressed by harvesting them at the immature or green stage, and/or by storing them either at low temperatures or in controlled atmospheres. However, mango fruits are susceptible to low temperature, they do not store well if they are harvested at full maturity, and the fruits generally fail to ripen properly if they are immature at the time of harvesting.

Genetic transformation of mango to date has focused on the improvement of fruit quality by controlling ethylene biosynthesis and, therefore, ripening. The strategy that has been utilized has involved the inhibition of expression of genes encoding ethylene biosynthetic enzymes by transformation with antisense genes. Three enzymes mediate the biosynthesis of ethylene: SAM synthase, ACC synthase, and ACC oxidase. ACC synthase and ACC oxidase in the antisense have been used in transformation studies involving tomato, and this strategy has resulted in slowly softening fruits to permit longer vine ripening and good shipping qualities (Oeller *et al.*, 1991; Gray *et al.*, 1992).

Gómez Lim (1997a) isolated ACC synthase and ACC oxidase from a mango cDNA library. He observed that ACC synthase cannot be detected in unripe fruit, and begins to appear in turning fruit and achieves maximum expression in ripe fruit (Gómez Lim, 1997a). Expression of ACC synthase appears earlier in the mesocarp than in the peel. In contrast, the expression of ACC oxidase is similar in both tissues, but is detectable before ACC synthase (Gómez Lim, 1997b). ACC oxidase is probably expressed before ACC synthase and ripening and therefore proceeds from the mesocarp outward toward the peel. ACC oxidase and ACC synthase first appear in the peel of ethylene-treated fruits.

2.1 Donor Gene

The only horticultural trait of mango that has been targeted for improvement by genetic transformation is the control of fruit ripening (Cruz Hernandez *et al.*, 1997). The following genes have been utilized in the antisense: alternative oxidase, ACC oxidase, and ACC synthase. Alternative oxidase cDNA was isolated by *in situ* hybridization of a ripe mango fruit mesocarp cDNA library. ACC oxidase cDNA was cloned from an *Arabidopsis thaliana* cDNA library, and ACC synthase was cloned by polymerase chain reaction (PCR)-amplification from DNA isolated from mango leaves (Gómez Lim, 1993; Cruz Hernandez and Gómez Lim, 1995; Cruz Hernandez *et al.*, 1997).

All of the genes were cloned at the *EcoRI* site in pBLUESCRIPT (Stratagene), and they

were recovered by *SacI-KpnI* double restriction. They were transferred to a pGEM7Zf(+) vector (Promega), flanking the genes with *XbaII* sites and cloned at the *XbaI* site in the pBI121 binary vector and controlled by the Cam 35S promoter.

2.2 Methods of Transformation

The accepted procedure for genetic transformation of mango was developed by Mathews *et al.* (1992, 1993), who reported genetic transformation of mango embryogenic cultures of “Hindi” and “Keitt”, respectively. These studies utilized two different disarmed, engineered strains of *Agrobacterium tumefaciens*, i.e., strain C58C1 containing pGV 3850::1103 with the selectable marker gene neophosphate transferase (*NPTII*) that confers resistance to the antibiotic kanamycin and driven by the cauliflower mosaic virus (CaMV) 35S promoter (Mathews *et al.*, 1993) and strain A208 containing the pTiT37-SE::pMON9749, a cointegrate vector, with genes for *NPTII* and the scorable marker β -glucuronidase (*gus* or *uidA*) both driven by the CaMV 35S promoter (Mathews *et al.*, 1992).

For transforming mango with ACC synthase, ACC oxidase and the EFE genes in antisense, the pBI121I/ACC, pBI121/AOX, and pBI121/EFE vectors were introduced into *A. tumefaciens* strain LBA4404 by electroporation. The *Agrobacterium* was activated with 30 mM acetosyringone for 16 h.

The mango embryogenic pathway has been utilized for transformation; details of this regeneration pathway have been reviewed by Mathews and Litz (1992), Litz *et al.* (1993, 1995, 2008), Litz and Lavi (1997), Litz and Gomez-Lim (2005), and Gómez Lim and Litz (2007). Embryogenic cultures of mango were induced from the nucellus of “Hindi” using standard induction medium consisting of modified B5 major salts (Gamborg *et al.*, 1968), MS (Murashige and Skoog, 1962) minor salts and organics, 400 mg l⁻¹ glutamine, 60 g l⁻¹ 2,4-dichlorophenoxyacetic acid (2,4-D), and 2 g l⁻¹ gellan gum (Litz *et al.*, 1982; DeWald *et al.*, 1989a). Cultures on semi-solid medium were maintained in darkness at 25 °C. Embryogenic cultures were maintained in liquid medium of the same formulation under diffuse light at 25 °C, and were transferred to fresh medium at weekly intervals.

2.3 Selection of Transformed Tissue for Resistance to Kanamycin Sulfate

Mathews and Litz (1990) determined that growth of nontransformed embryogenic suspension cultures was inhibited by $12.5 \mu\text{g ml}^{-1}$ kanamycin sulfate; whereas, growth of larger proembryonic masses was inhibited on semi-solid medium by $200 \mu\text{g ml}^{-1}$ kanamycin sulfate. Embryogenic suspension cultures in their logarithmic phase of growth were passed through sterile filtration fabric ($1000 \mu\text{m}$ pore size), and approximately 300 mg of the large fraction ($>1000 \mu\text{m}$) was abraded with a sterile brush on sterile filter paper. Abraded embryogenic cultures were co-cultured with a log phase culture of acetosyringone-activated *A. tumefaciens* in 50 ml of liquid medium for 3 days. *Agrobacterium* contained vectors pB121I/ACC, pBI121/AOX, and pBI121/EFE.

All genetic transformation reports have followed a two-step selection procedure (Mathews *et al.*, 1992, 1993; Cruz Hernandez *et al.*, 1997). Embryogenic cultures were transferred to semi-solid maintenance medium containing 100 mg l^{-1} cefotaxime and 100 mg l^{-1} kanamycin sulfate. Following the appearance of light colored segments on the co-cultured tissue, putatively transformed embryogenic cultures were transferred to semi-solid maintenance medium containing 200 mg l^{-1} kanamycin sulfate and 100 mg l^{-1} cefotaxime. Cultures in liquid medium were maintained in 125 ml Erlenmeyer flasks under diffuse light in the laboratory at 125 rpm. Cultures on semi-solid medium were maintained in darkness at 25°C .

Putatively transformed embryogenic cultures were transferred to somatic embryo maturation medium containing 200 mg l^{-1} kanamycin and 100 mg l^{-1} cefotaxime. Somatic embryo maturation medium consisted of B5 major salts, MS minor salts and organics, 400 mg l^{-1} glutamine, 60 g l^{-1} sucrose, and 20% (v/v) filtered sterile coconut water from freshly harvested immature nuts (DeWald *et al.*, 1989b). Cultures were maintained in darkness at 25°C .

2.4 Regeneration of Whole Plants

Germinating somatic embryos were moved to light conditions ($60 \mu\text{mol s}^{-1} \text{ m}^{-2}$), and when shoots began to emerge, they were transferred to minimal

medium consisting of B5 major salts, MS minor salts and organics, 30 g l^{-1} sucrose, 0.1% activated charcoal and 2.0 g l^{-1} gellan gum. Of the different procedures that have been attempted to enhance plant recovery, i.e., conversion, micrografting and *ex vitro* grating of somatic embryo shoots on seedling rootstocks has been most effective (Litz, unpublished data).

2.5 Testing

Mango trees are propagated vegetatively. Consequently, many of the outstanding cultivars of traditional mango-producing countries, i.e., India, Pakistan, Myanmar, Thailand, Malaysia, etc., are several hundred years' old. The time required to determine the stability of inheritance of transgenes in superior tree selections would require at least two decades and possibly longer, and is thereby not feasible. Likewise, the long juvenile period of 7 years and the 6 or 7 more years required to evaluate whether productivity has been affected preclude classical approaches to evaluate plants in a breeding program.

Transformation was therefore confirmed by (1) growth and development of putatively transformed embryogenic cultures and somatic embryos in the presence of growth-limiting kanamycin sulfate, (2) the 5-bromo-4-chloro-3-indolyl- β -D-glucuronic acid (X-Gluc) reaction for the presence of the *uidA* gene, (3) amplification of the *nptII* gene by PCR, and (4) Southern blot hybridization.

2.6 Specific Regulatory Measures Adopted

Transgenic mangoes have been maintained in a nursery, and have not been transferred to the field.

3. FUTURE ROAD MAP

3.1 Expected Products

It is anticipated that postharvest handling and storage of mango fruit will be greatly improved as a result of this strategy. It has been estimated that postharvest losses of mango fruit in developing countries can exceed 70% of the total production. The losses are due to the development of

anthracnose in rapidly ripening fruit and to the poor infrastructure, i.e., storage facilities, roads, etc. in many mango-producing countries. By lowering the postharvest losses of fruit, the profitability of the industry should be greatly improved, and lower acreage of mango groves would be needed to meet local and international demands.

3.2 Addressing Risks and Concerns

It is not anticipated that there will be any issues related to human health and the environment; however, the introduction of transgenic mangoes into traditional mango-producing areas could have a major impact on patterns of farming. Because of the large postharvest losses of fruit and vegetables in the tropics, there must be greater production to meet demand. This innovation should enable producers to devote less acreage to production of mango, and this would result in much lower production costs, for example, fungicides, fertilizer, etc.

3.3 Expected Technologies

Cruz Hernandez *et al.* (2000) reported the transient genetic transformation of embryogenic “Kensington Pride” and “Carabao” cultures using a biolistic approach and two vectors: (1) pBI426 with *GUS-NPTII* under the control of a double CaMV 35S promoter and (2) pBINGfp-Ser, which contains *NPTII* and the green fluorescent protein gene (*gfp*). Although stable transformants were not recovered, biolistic-mediated transformation might facilitate the transformation procedure with this species.

Ideally, the ACC oxidase, ACC synthase, and *EFE* genes in antisense should be expressed under the influence of a mango fruit ripening-specific promoter. However, there has been no progress in this respect. Other genes that suppress ethylene biosynthesis, including ACC deaminase (Klee *et al.*, 1991) and SAM hydrolase (Good *et al.*, 1994) should also be evaluated for their effects on controlling mango fruit ripening. These genes have both been isolated from microorganisms, and this may cause increased scrutiny with respect to health and safety issues.

3.4 Economic Consequences

This strategy for improving shelf life of mango should have a major impact on the economics of fruit production in developing countries (see Section 3.1). By dramatically reducing postharvest losses, it should be possible to produce more marketable fruits on less acreage. The acceptance of transgenic mango fruits in export markets is an uncertainty, although it is quite likely that they will be accepted quickly in producing countries.

Avocado

Richard E. Litz

Tropical Research and Education Center, University of Florida, Homestead, FL, USA

1. INTRODUCTION

1.1 History, Origin, and Distribution

The avocado is believed to have its center of origin in the humid tropical highlands of central America, embracing Chiapas in southern Mexico, Guatemala, and Honduras. The etymology of avocado is the Nahuatl “ahuacatl”, which was transliterated into Spanish as “aguacate”. According to Smith (1966, 1969), the Mexican race was identified and possibly selected 9000–10 000 years ago. Gama (1994) believed that domestication of avocado probably occurred over a long period of time among meso-American cultures. The avocado is now grown in most of the tropical and subtropical regions.

1.2 Botanical Descriptions

The Lauraceae is an ancient group that consists primarily of tree species, some of which are important, i.e., avocado (*Persea americana*), bay leaf (*Laurus nobilis*), camphor (*Cinnamomum camphora*), and cinnamon (*Cinnamomum zeylanicum*). The genus *Persea* may have originated in Gondwanaland, and radiated to Asia and North America via Europe. The genus spread to South America via Antarctica during the Paleocene, and when the land bridge between North and South America was established during the late Neocene, the genus was reunited. The Southeast Asian *Machilus*, *Nothaphoebe*, and *Alseodaphne* genera

may be congeneric with *Persea* (Kostermans, 1952). Extensive speciation within *Persea* occurred in central America (Scora and Bergh, 1990). Wild *P. americana* trees occur in the forests of these tropical highlands (Kopp, 1966). There are two subgenera within *Persea*, i.e., *Eriodaphne* (South America) and *Persea* (North America) (Kopp, 1966). Scora *et al.* (2002) identified three species within the subgenus *Persea*: *P. schiedeana* Nees, *P. parviflora* Williams, and *P. americana* Mill.

Within *P. americana*, there are eight well-defined subspecies or geographical races that evolved in different climatic environments and in geographical isolation from each other (Scora *et al.*, 2002). The subspecies include *P. americana* var. *nubigena* (Williams) Kopp, var. *steyermarkii* Allen, var. *zentmyerii* Schieber and Bergh, var. *floccosa* Mez., and var. *tolimanensis* Zentmyer and Schieber. Three other subspecies comprise the common avocado (Bergh and Ellstrand, 1986), and include the Mexican *P. americana* var. *drymifolia* (Schlect. and Cham.) Blake, which originated in the highlands of south-central Mexico, the Guatemalan subspecies *P. americana* var. *guatemalensis* Williams, which originated in medium elevations in the tropics, and the Antillean or West Indian subspecies *P. americana* var. *americana* Mill., which originated in the humid lowlands of the central American Pacific coast (Popenoe, 1941; Storey *et al.*, 1986). The ancestry of the Guatemalan race may include var. *nubigena*, var. *steyermarkii*, var. *zentmyerii*, and var. *tolimanensis* (Kopp, 1966; Schieber and Bergh, 1987; Furnier *et al.*, 1990). The Antillean

subspecies may have evolved from the Mexican subspecies according to Williams (1976, 1977).

The avocado tree is evergreen, and is approximately 20 m high at maturity. It is supported by a shallow unsuberized secondary root system, although anchorage roots can penetrate to 3–4 m (Whiley, 1992). Flowers are borne on the branch terminals as panicles of cymes. The fruit is a large, fleshy, pyriform, or globose berry containing a single seed. The chromosome number of the species is $2n = 2x = 24$ (Garcia, 1975), and the haploid genome size is 8.83×10^8 bp (base pair), which is relatively small, only 6× the size of *Arabidopsis thaliana* and similar to that of tomato (Arumuganathan and Earle, 1991).

1.3 Economic Importance

World production of avocados was estimated to be 3 271 962 t in 2005 (FAOSTAT, 2006). The greatest production occurs in Mexico (1 021 515 t), Indonesia (263 575 t), the United States (256 189 t), Colombia (185 811 t), Brazil (182 000 t), Chile (163 000 t), and Dominican Republic (140 000 t). Other important producers are South Africa, China, Venezuela, and Peru. Although avocado is normally consumed as a fresh fruit, it is also a rich source of oil.

The international trade in fresh fruit is very important, with an estimated value of avocado exports in 2004 of US\$606 611 000 (FAOSTAT, 2006). Leading exporting countries include Mexico (US\$211 255 000), Chile (US\$94 624 000), and Spain (US\$86 316 000). Other important exporting countries include Israel, New Zealand, and South Africa. The EU and North America are the biggest importers of avocados, US\$387 012 000 and US\$213 275 000, respectively (FAOSTAT, 2006). “Hass” is the most important export avocado.

1.4 Traditional Breeding

Within its native habitat, the avocado tree is a large spreading canopy species, and like other tropical forest trees, it is genetically heterozygous. Avocado has a long juvenile period of approximately 7 years, and several more years are required to assess productivity of seedling trees. Although the

avocado tree flowers profusely, there is a very high incidence of floral abscission and immature fruit drop. The flowering pattern is dichogamous, protogynous, and synchronous (Whiley, 1992); each flower opens twice during two consecutive days. As a consequence, all open flowers are either functionally male or female. Avocado cultivars are identified on the basis of their flowering pattern, depending on whether the flowers are female in the morning (type A) or in the afternoon (type B), and in this way, self-pollination is prevented.

Conventional breeding programs for avocado improvement have been moderately successful, despite the fact that the leading cultivars are almost all derived from open pollinations. The current status of avocado breeding has been reviewed by Bergh and Lahav (1996) and Lahav and Lavi (2002). Because of the lack of segregating seedling populations, the long juvenile period and the time required for assessing the mature phenotype, very little is known about the inheritance of horticultural traits. According to Lavi *et al.* (1993a, b), most morphological traits are probably coded by several loci with several alleles in each locus. Bergh and Lahav (1996) suggested that the dwarf trait of *P. schiedeana* can be attributed to a single gene.

Many avocado cultivars are hybrids that involve two or more subspecies or races. “Hass” and “Fuerte” are Guatemalan × Mexican hybrids. Early California cultivars originated either as selections made in Mexico and central America, e.g., “Benik”, “Itzamna” and “Nabal”, or from imported seeds, e.g., “Dickinson” and “Fuerte” (Bergh, 1957). “Bacon”, “Hass”, “Pinkerton”, “Reed”, and “Zutano” were selected from open-pollinated seedlings in California, USA, and are grown in Mediterranean and subtropical climates. In South Florida, USA, and other tropical regions, West Indian and Guatemalan × West Indian hybrids are grown.

Conventional avocado breeding has focused on improvement of both rootstocks and scions. The most serious threat to avocado production is the disease *Phytophthora* root rot (PRR), which is caused by the soil-borne pathogenic oomycete *Phytophthora cinnamomi* Rands (Coffey, 1987; Whiley, 1992; Ben-Ya’acov and Michelson, 1995). Within the *Persea* subgenus, there is no resistance to PRR, although resistance to PRR occurs in the subgenus *Eriodaphne*. Species in the latter group

are sexually and graft incompatible with species in the subgenus *Persea* according to Zentmyer (1980), Bergh and Ellstrand (1986), and Lahav and Lavi (2002). The rootstock “Duke” and its progeny, “Duke 7”, “Barr-Duke” and “D9”, “Thomas” and “G6” are tolerant to PRR. Although “Martin Grande” (G755) (*P. schiedeana* × *P. americana*) (Ellstrand *et al.*, 1986) is PRR tolerant, the trees are unproductive. Rootstocks with tolerance to PRR often show no tolerance to the related pathogen, *Phytophthora citricola* (Tsao *et al.*, 1992).

Several major production areas are in the semiarid or arid environments where irrigation water is either scarce or somewhat saline. As a result, rootstocks are being sought that show tolerance to saline conditions. Within the different subspecies/races, West Indian avocados generally have the most resistance to saline conditions, whereas Mexican avocados have the least resistance (Kadman and Ben-Ya’acov, 1976). West Indian avocados also have greater resistance to calcium-induced chlorosis (Ben-Ya’acov, 1972). West Indian avocados do not tolerate heavy and waterlogged soils (Ben-Ya’acov *et al.*, 1974). Production costs could be lowered if the large growth habit of the avocado tree could be controlled with dwarfing rootstocks. The “Colin V-33” selection, used either as an interstock or as a rootstock, has been demonstrated to confer a dwarf habit to the scion according to Sánchez-Colin and Barrientos-Priego (1987).

There are several breeding objectives for scion selections. The market standard for avocado is the black-skinned “Hass”, although the green-skinned “Fuerte” also holds a small, yet significant, market share. Fruit ideally should be approximately 250–350 g (Lahav and Lavi, 2002), with a small seed, either of pyriform or of ovate shape, and an easily removable peel. Many of the cultivars that have emerged from breeding programs have fruits that resemble “Hass”, and indeed, complement “Hass” by bearing in the off-season, e.g., “Gwen”, “Jim”, “Lamb Hass”, and “Reed”. The tropical avocados (West Indian and West Indian × Guatemalan hybrids) are much more heterogeneous with respect to shape and size.

Mexican avocados are quite susceptible to anthracnose, caused by *Colletotrichum gloeosporioides* Penz. (Ruehle, 1963). There are varying levels of resistance to *Cercospora* spot or blotch, caused

by *Pseudocercospora purpurea* Cooke, and avocado scab, caused by *Sphaceloma perseae* Jenkins in certain avocado cultivars.

Avocado fruits of Mexican, and hybrids with Mexican parentage, are strongly climacteric (Adato and Gazit, 1977). There is a fixed climacteric phase followed by a variable lag phase during which low concentrations of ethylene are produced (Eaks, 1980), and this in turn triggers the climacteric as sensitivity to ethylene increases (McMurchie *et al.*, 1972). After ripening has been initiated, it cannot be arrested. Fruits of Guatemalan and Mexican cultivars and their hybrids mature but do not directly ripen, and can be stored “on the tree” for 2–4 months (Whiley, 1992); ripening occurs after the fruits have been harvested. In contrast, West Indian and West Indian × Guatemalan cultivars mature and ripen “on the tree”, and must be picked at maturity. By exploiting this habit and production in different climatic niches, it has been possible for growers in California, USA, to provide “Hass” fruits almost year round (Griswold, 1945). They have been able to market a uniform product; however, year-round production of West Indian and West Indian × Guatemalan fruit in the tropics requires several cultivars, each with a different maturity date (Crane *et al.*, 1996), and there is no market standard for these avocados.

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

The avocado tree is a genetically heterogeneous species with a complex breeding system. It has a long juvenile period of approximately 7 years and an equally long period before many mature tree characteristics that impact production can be evaluated. Although there has been some limited success in identifying molecular markers that are associated with phenotypic characteristics, marker-assisted breeding has still not made an impact on avocado improvement. The most important breeding objectives, namely resistance to PRR in rootstocks and improvement of the postharvest storage life of West Indian and West Indian × Guatemalan selections, cannot be achieved by conventional breeding. Particularly for addressing these issues, therefore, a transgenic approach is essential.

2. DEVELOPMENT OF TRANSGENIC AVOCADOS

Control of ripening of avocado fruit is being addressed. Several genes that have been implicated in ripening of avocado fruit have been cloned. A ripening-specific cellulase (*pAV5*) was the first gene to be identified in avocado (Christoffersen *et al.*, 1984). Tucker *et al.* (1987) used *pAV5* to screen a complementary DNA (cDNA) library from ripe "Hass" fruit, and isolated *pAV363*. Cass *et al.* (1990) screened an avocado genomic library with the cellulase cDNA probe and identified *cell*, which is homologous with cellulase cDNA. Only *cell* transcripts have been detected in mesocarp of ripe avocado fruit, and it has also been detected in the fruit abscission zone (Tonutti *et al.*, 1995). Expression of *cell* in the mesocarp during fruit ripening is associated with abscission of mature avocado fruits.

Bozak *et al.* (1990, 1992) and O'Keefe *et al.* (1992) cloned a cytochrome P-450 from the mesocarp of ripe avocado fruit. The gene was designated as *CYP71A1*, and there is accumulation of the *CYP71A1* gene product during ripening, although the function of *CYP71A1* is uncertain. Avocado polygalacturonase (*PG*) has been isolated from a cDNA library by heterologous hybridization with a tomato cDNA probe, and Wakabayashi and Huber (2001) isolated an endo-*PG* from avocado mesocarp. *AVOe3* messenger-RNA has been identified as a ripening-related gene and might be involved in ethylene biosynthesis (McGarvey *et al.*, 1992). Twenty-three cDNA clones have been identified by differential screening of a cDNA library of cold-stored avocado fruit (Dopico *et al.*, 1993). Six of the clones showed increased expression during cold storage and normal ripening, and were homologous with *PG*, endochitinase, a cysteine proteinase inhibitor, and several stress-related proteins.

Although PRR is the most serious production problem of avocado, there have been no reports of the identification of genes that might control this disease. Since there is no resistance within the subgenus *Persea*, candidate genes would have to be cloned in species within subgenus *Eriodaphne*, e.g., *Persea borbonia*, *Persea cinerascens*, *Persea pachypoda*, etc., that are highly resistant to the disease.

2.1 Donor Gene

In order to address postharvest storage of avocado fruit by controlling ethylene biosynthesis, the bacteriophage gene S-adenosyl-L-methionine (SAM) hydrolase (*SAMase*) under the control of a cellulase promoter isolated from avocado fruit has been utilized (Hughes *et al.*, 1987). *SAMase* in the binary vector pAG4092, which used the backbone of the pPZP200 binary vector, was utilized (Agritope, 1999). The pAG4092 has the *NPTII* gene that encodes resistance to the antibiotic kanamycin under the AGT01 promoter located near the left border and the *samK* gene driven by a fruit-specific avocado cellulase promoter located near the right border (Agritope, 1999). The *samK* gene is a modified *samase* and encodes for *SAMase* and catalyzes the conversion of SAM to methylthioadenosine (Good *et al.*, 1994). Since SAM is the metabolic precursor of 1-aminocyclopropane-1-carboxylic acid, the proximal precursor of ethylene, the depleted SAM pool inhibits ethylene biosynthesis (Good *et al.*, 1994; Kramer *et al.*, 1997).

In the absence of candidate genes that might confer resistance to PRR, avocado has been transformed with an antifungal defensin gene *pdf1.2*. The defensin gene was driven by the cauliflower mosaic virus 35S promoter in binary vector pGPTV; the construct also contained the *uidA* reporter gene (GUS— β -glucuronidase) and the *bar* gene for resistance to phosphinothricin, the active ingredient of the herbicide Finale[®]. The *pdf1.2* gene was isolated from *A. thaliana*, and is induced by different phytopathogenic fungi: *Alternaria raphans*, *Alternaria brassicola*, *Fusarium oxysporum* f. sp. *matthiolae*, *F. oxysporum* f. sp. *raphans*, etc. (Epple *et al.*, 1997).

2.2 Transformation Methods

The standard procedure for transforming avocado has involved the use of highly embryogenic cultures (Witjaksono and Litz, 1999a, b; Witjaksono *et al.*, 1999), and has been based upon the initial study of Cruz-Hernandez *et al.* (1998). The complete suppression of embryogenic avocado culture growth occurred on semisolid medium containing 200 mg l⁻¹ kanamycin sulfate. Cruz-Hernandez

et al. (1998) described a two-step selection protocol for genetic transformation of avocado. Embryogenic cultures on semisolid maintenance medium were gently abraded with a soft camel hairbrush, and then incubated with acetosyringone-activated *Agrobacterium tumefaciens* strain 9749 ASE2, which contained a co-integrate vector pMON9749 with a selectable kanamycin sulfate-resistant marker (*nptII*—neomycin phosphotransferase II) and *uid* in liquid maintenance medium for 3 days at 100 rpm. *A. tumefaciens* was eliminated by incubating the cultures in maintenance medium supplemented with 50 mg l⁻¹ kanamycin sulfate and 200 mg l⁻¹ cefotaxime. There was an initial selection for antibiotic resistance in liquid maintenance medium containing 50 mg l⁻¹ kanamycin sulfate for 2–4 months, and a second, more intensive selection with 100 mg l⁻¹ kanamycin sulfate for 2 months. The cultures were finally cultured in maintenance medium containing 200 mg l⁻¹ kanamycin sulfate to eliminate chimaeras. Somatic embryo development occurred on maturation medium without kanamycin sulfate, followed by subculture onto maturation medium containing 200 mg l⁻¹ kanamycin sulfate. Transgenic plants were not regenerated in this early study.

For transforming avocado with *samase* and *pdf1.2*, the pAG4092 and pGPTV-BAR-AFP vectors, respectively, were introduced into *A. tumefaciens* EHA 105 by electroporation. The *Agrobacterium* was activated with 30 mM acetosyringone for 16 h. Embryogenic “Suardia” cultures were genetically transformed with *samase*, and embryogenic “Hass” cultures were transformed with *pdf1.2*. The embryogenic cultures were induced from zygotic embryos extracted from immature avocado fruit. Induction medium consisted of semisolid B5 (Gamborg *et al.*, 1968) major salts, Murashige and Skoog (MS) (Murashige and Skoog, 1962) minor salts, 0.1 mg l⁻¹ thiamine HCl, 100 mg l⁻¹ myo-inositol, 30 g l⁻¹ sucrose, 0.41 μM picloram, and 8.0 g l⁻¹ agar (Witjaksono and Litz, 1999a). Cultures were incubated in darkness at 25 °C.

Embryogenic cultures were maintained either on semisolid medium (MSP), MS basal medium with 0.1 mg l⁻¹ thiamine HCl, 100 mg l⁻¹ myo-inositol, 30 g l⁻¹ sucrose, and 0.41 μM picloram, or as suspension cultures. For suspension cultures, the nitrogen component of MS was modified

accordingly: 12 mg l⁻¹ NH₄NO₃ and 30.3 mg l⁻¹ KNO₃ (MS3:1P). Approximately 200 mg of embryogenic cultures was inoculated into 40 ml of liquid MS1:3P medium in 125 ml Erlenmeyer flasks, which were sealed and maintained on a rotary shaker at 100 rpm and 25 °C under subdued light. Subcultures were at 2-week intervals.

2.3 Selection of Transformed Tissue

2.3.1 *Samase*

The two-step transformation procedure described by Cruz-Hernandez *et al.* (1998) was modified (Efendi, 2003). Embryogenic “Suardia” suspension cultures in their logarithmic (log) phase of growth were passed through sterile filtration fabric (1000 μm pore size), and approximately 300 mg of the large fraction (>1000 μm) was abraded with a sterile brush on sterile filter paper. Abraded embryogenic cultures were co-cultured with log phase acetosyringone-activated *A. tumefaciens* in 50 ml of liquid medium for 3 days. *Agrobacterium* contained vector pAG4092. An embryogenic suspension culture in its log phase of growth was sieved through sterile nylon filtration fabric (mesh size 1.8 mm), and the smaller fraction was used.

The small fraction was subcultured into 80 ml fresh MS 3:1 medium in 250-ml Erlenmeyer flasks supplemented with 50 mg l⁻¹ kanamycin sulfate and 100 mg l⁻¹ spectinomycin to which a 1.0 ml aliquot of 6-h-old acetosyringone-activated *A. tumefaciens* was added. Flasks were maintained at 125 rpm in darkness at 25 °C for 3 days, when the cultures were transferred into fresh MSP 3:1 medium supplemented with 200 mg l⁻¹ cefotaxime and 500 mg l⁻¹ carbenicillin for 8 days with a change of medium after 2 days. Embryogenic cultures were then transferred into fresh MSP 3:1 medium supplemented with 50 mg l⁻¹ kanamycin sulfate and then 4 days later to fresh medium with 100 mg l⁻¹ kanamycin sulfate. Cultures were maintained in MS 3:1 medium supplemented with 100 mg l⁻¹ kanamycin sulfate. Somatic embryo development occurred on semisolid MS medium supplemented with 30 g l⁻¹ sucrose, 20% (v/v) filter-sterile coconut water, and 100–300 mg l⁻¹

kanamycin sulfate (Witjaksono and Litz, 1999b, 2002).

2.3.2 *pdf1.2*

The inhibition of “Hass” embryogenic suspension culture growth by phosphinothricin was reported by Raharjo *et al.* (2008), who reported that 3 mg l^{-1} phosphinothricin inhibited the growth of embryogenic cultures, and was utilized as the basis for selection for cultures transformed with the pGPTV-BAR-AFP construct. The large fraction of embryogenic “Hass” suspension cultures in their log growth phase was collected on sterile filtration fabric ($1000\text{ }\mu\text{m}$ pore size), and approximately 300 mg was abraded with a sterile brush on sterile filter paper. The tissue was then co-cultured with log phase acetosyringone-activated *A. tumefaciens* strain EHA 105 with pGPTV-BAR-AFP in 50 ml of liquid medium for 3 days. The proembryonic masses (PEMs) were then transferred to liquid maintenance medium supplemented with 200 mg l^{-1} cefotaxime and 500 mg l^{-1} carbenicillin, and subcultured 2 weeks later into fresh liquid maintenance medium with 200 mg l^{-1} cefotaxime, 500 mg l^{-1} carbenicillin, and 3.0 g l^{-1} phosphinothricin for 3 months. Embryogenic cultures were selected continuously with phosphinothricin, and stained periodically for *uidA* until they were apparently completely transformed. Transformed embryogenic cultures were transferred to somatic embryo development medium that also contained 3 mg l^{-1} phosphinothricin.

2.4 Regeneration of Whole Plants

The shoots from somatic embryos transformed with *pdf1.2* (“Hass”) and *samase* (“Suardia”) were excised and grafted *in vitro* on decapitated “Peterson” seedling rootstocks (Raharjo and Litz, 2005). Rapidly growing transgenic shoots were excised and grafted on “Peterson” rootstocks in the nursery. In order to assure that *pdf1.2* was expressed in roots as well as shoots of “Hass”, *pdf1.2*-transformed scion shoots were air layered, and self-rooted plants were recovered. “Hass” plants contained the *bar* gene, and were resistant to the herbicide Finale, whose active ingredient is

phosphinothricin. In order to expedite flowering in “Suardia” shoots with *samase*, budwood was grafted on “Hass” and “Lula” interstocks.

2.5 Testing

Avocado is a perennial plant with long juvenile period. It is, therefore, impractical to study the inheritance of transgenes in avocado because of the time involved. Because fruit trees are clones, often of great antiquity, the goal of transformation is to modify existing cultivars for one or more horticultural traits. The transgenic plants have been under assessment in a nursery for $2\frac{1}{2}$ years. We have not observed any phenotypic changes in “Hass” plants containing *pdf1.2*, although alterations in plant architecture and leaf morphology have been observed with “Suardia” containing *samase*.

2.6 Regulatory Measures

Transgenic avocado plants have not been transferred from the nursery to the field; however, “Hass” plants containing *pdf1.2* were shipped to California for greenhouse observation and this was under the APHIS (Animal Plant Health Inspection Service (USA)) and California Department of Plant Industries regulations.

3. FUTURE ROAD MAP

3.1 Expected Products

“Hass” avocado that expresses the *pdf1.2* gene constitutively should demonstrate enhanced resistance to fungal pathogens. This should be significant for control of diseases that affect fruit and foliage, such as anthracnose, caused by *C. gloeosporioides*, and *Cercospora* spot caused by *P. purpurea*, and important diseases of rootstocks caused by *Rosellinia necatrix* and other pathogens. “Suardia” transformed with *samase* under the control of an avocado fruit-specific promoter should demonstrate inhibition of ethylene during fruit development. This should enable prolonged storage of fruit “on the tree” and in postharvest storage. This should have a great effect on the

rationalization of tropical avocado cultivars, and create a market standard for Antillean avocados.

3.2 Addressing Risks and Concerns

There should not be any human health or environmental risk with either of these transgenic avocados, although the bacteriophage origin of *samase* may require extra scrutiny before “Suardia” is cleared for commercial production. Both transgenic avocados may find ready acceptance in tropical producing regions for local consumption. Currently, the EU is the largest market for avocado fruit, and acceptance of transgenic fruit there is still uncertain.

3.3 Expected Technologies

Although *samase* is expressed under the control of an avocado fruit-specific promoter, such organ-specific and development-specific promoters are still rare in most tree species. Root-specific promoters would be very useful for controlling pathogenesis-related and defensin genes that target pathogens that attack the root system of avocado, e.g., *P. cinnamomi*. *Persea* species within the *Eriodaphne* are the only source of genes that confer immunity to PRR, and every possible effort should be undertaken to identify and clone these genes.

3.4 Economic Consequences

Success of the *samase* strategy for blocking the biosynthesis of ethylene in avocado fruit is projected to have a major impact on avocado production, particularly with respect to the tropical or Antillean cultivars. Currently, there is no market standard for Antillean avocados. The fruits ripen “on the tree” and have poor postharvest storage life. As a consequence, Florida, USA, avocado producers must grow more than 20 cultivars in order to supply markets for most of the year (Crane *et al.*, 1996). By blocking ethylene biosynthesis, it is our expectation that transgenic Antillean avocados could be stored “on the tree” and could compete with the Mexican and Mexican × Guatemalan cultivars.

Enhancing disease resistance in roots, fruit, and foliage of avocado using the *afp1.2* strategy can only improve the sustainability of avocado production in the humid tropics and the subtropics.

Kiwifruit

Patricia Gutiérrez-Pesce and Eddo Rugini

Dipartimento di Produzione Vegetale, Università degli Studi della Tuscia, Viterbo, Italy

1. INTRODUCTION

1.1 History, Origin, and Distribution

The name *Actinidia*, attributed by Nathaniel Wallich to plants found in Nepal, derives from Greek *aktis*, which means irradiation due to the radiate stigma of the flowers. The common name, kiwi or kiwifruit, is accepted worldwide for the resemblance with the bird symbol of New Zealand where it was cultivated since 1904 (Ferguson, 1999). Other names were attributed in other countries: “Chinese gooseberries” in the United States, “Groseille de China” in France, “Mao-yantao” or “Mao-ertao”, and “Yang-tao” or “Yang-taw”, with bristly hair and soft hair, respectively, in China, “Actinidia” the plant and “kiwi” the fruit, in Italy. It has become a common fruit over the last 30 years in all the markets of the world.

Actinidia is widespread in the temperate and subtropical regions of the Asian continent. It is considered native to China, since most of the species are spread in the Yangtze river valley offering a bulk of germplasm resources. These huge resources are of immense value in developing new varieties. Among them the two species with the most important economic value are *Actinidia chinensis* var. *chinensis* growing more in the lowlands in the eastern provinces, and *Actinidia deliciosa* in the western, inland, colder areas (Huang and Ferguson, 2001). Until 20 years ago they were classified as one species; however,

A. chinensis fruit is almost hairless and the flesh ranges from a lime green to bright yellow and fruits are sweeter than those of *A. deliciosa*. The most important cultivars grown in the world belong to these two species (Chen, 2003). Other species have been found in the Korea, Japan, Nepal, India, Vietnam, and Russia (Ferguson, 1990a). In these areas, the fruits were collected from the wild, and several of them were introduced for cultivation few years ago and some of them have been selected for the breeding programs.

1.2 Botanical Description

Cultivated kiwi varieties of *A. deliciosa* are characterized by vigorous growth, flexible trunks, and superficial root system, thus strong support structures are needed, increasing the costs of establishment of the orchards. On the contrary *A. chinensis* has a compact vegetative habit (Testolin *et al.*, 1996). Long flexible and climbing vines with large leaves and long internodes are heavily damaged in windy areas where it is possible to observe lower pollination by bees, breaking flowers, leaves, and branches, physiological dysfunctions resulting in hydric disequilibria, causing leaves to dry up, and subsequently, defoliation. The original microenvironment is characterized by high atmospheric relative humidity, mild temperatures, and a limited light intensity during the summer period. Winter and fall frost (−20 °C) can crack bark while late spring frosts, especially

during blossoms, cause necrosis in flowers and tender shoots. Winter temperatures of 8–10°C ensure the chilling requirement for blossom and the total cold timing should be between 1500 and 2000 h for 8°C and 2000 and 3000 h for 10°C (Sale, 1983). The most widely cultivated kiwifruit cultivar, Hayward, needs only 400–600 h below 7°C. In some areas with low winter chilling, spraying dormancy-breaking agents are necessary to increase bud break and fertility (Costa *et al.*, 1997).

Irrigation is essential for keeping soils fresh and also for maintaining high atmospheric humidity in the kiwi orchard. The soil must be rich in organic matter with a neutral or slightly acid pH. Plants do not tolerate highly concentrated nitrates or soluble chlorides in low absorbent soils; thereby soils must have a good drainage system and be rich in humus (Revilla *et al.*, 1992).

Dioecism in kiwi represents a big problem not only for the presence of 15–20% of unproductive pollinators but also for the difficulties in pollination due to asynchrony of blossom with pollinators (Testolin *et al.*, 1990). Flowers are less attractive to insects; and pollen is unsuitable for insect pollination because it is not sticky enough and unsuitable for wind pollination because it is heavy. Fecundation of all ovules is necessary because large fruit size is correlated with the number of seeds. Regular pollination is assured either by artificial pollination or by grafting staminate twigs on the pistillate plant. Dioecism in kiwi is not well defined, both pistils and stamens develop normally but few weeks before blooming one of the two stops growing (Schmid, 1978). Inconstant male and female plants (plants with hermaphrodite flowers) of *A. deliciosa* (Ferguson, 1984; Hirsch *et al.*, 1990; Messina *et al.*, 1990; McNeilage, 1991a, b; Ossani, 1994) and *A. chinensis* (Tang and Jiang, 1995) have been reported. The use of these inconstant staminate plants in genetic improvement programs has given heterogeneous results. Crossing with pistillate plants resulted in only 1–2% of hermaphroditism (Seal and McNeilage, 1989; Buscaroli and Bulzacca, 1994; Testolin *et al.*, 1995; Ferguson *et al.*, 1996); however, in both species the fruit size of hermaphrodite flowers is too small. Chromosome doubling of these plants does not increase the size of the fruits (E. Rugini, personal communication).

1.2.1 Taxonomy

The first botanical name given to the fruit worldwide known as “kiwifruit” was *A. chinensis* by Planchon in 1847. Then, a description based on the smooth skinned and hairy fruit was given by Burbank in 1911. The first botanical distinction of kiwifruit was made by Chevalier (1941) based on the same character that Burbank described, proposing the name of *A. chinensis* var. *deliciosa* for the hairy variety. Later, Liang and Ferguson (1986) proposed the name of *A. chinensis* for the plants with soft-haired fruit, and *A. deliciosa* for the plants with stiff-haired fruits. Since then, the accepted botanical name is *A. deliciosa* (A. Chev.), C.F. Liang and A.R. Ferguson. In the 1990s, cellular biology and molecular systematics and phylogeny have been extensively studied (Cipriani *et al.*, 1995, 1996; Xiao and Hirsch, 1996). In 1998, it was reported that the chloroplast DNA is paternally inherited in the genus *Actinidia*, thus *A. chinensis* is the paternal progenitor of *A. deliciosa* (Cipriani *et al.*, 1998). This discovery confirmed the hypothesis of Testolin and Ferguson (1997) who affirmed that hexaploid *A. deliciosa* ($2n = 174$) derived by polyploidization of the diploid *A. chinensis* ($2n = 58$). These results have been further confirmed by Hirsch *et al.* (2002) who studied the relationships of the two species through chemical means by analyzing their coumarin content (fraxin and esculin). These substances were not present in other *Actinidia* species belonging to the section of the genus.

Over 110 *taxa* and 60 species, belonging to four sections (*Leiocarpae*, *Maculatae*, *Stringosae*, and *Stellatae*) are considered within the genus *Actinidia* Lindl of the *Actinidiaceae* family, and many of those have edible fruit (Liang, 1984); however, the systematical botanic is still under classification because it is a dioecious and polyploid species and these features make genetic studies difficult (Huang *et al.*, 1999). *A. deliciosa*, *A. chinensis*, *Actinidia setosa* are considered to belong to the same complex due to similar morphological traits, and until recently they have been treated as *A. chinensis* by botanists (Liang, 1984), although they differed in ploidy level, fruit size, shape, and taste. The polyploid races of the complex may be derived from the diploid *A. chinensis* genotypes without there being a contribution from any other *Actinidia*

species (Testolin and Ferguson, 1997). The fruit size is directly correlated to the ploidy level and inversely correlated to the plant frost resistance. Only the female cultivar “Hayward” of *A. deliciosa* is intensively cultivated all over the world followed by the pollinator of the male cultivar Tomuri or Matua. Recently, Chinese breeders have released 15 new cultivars deriving from the germplasm source of *A. chinensis*, and these cultivars are widely used in China (Chen, 2003).

Molecular approaches have been attempted for understanding the taxonomy of the genus and for identifying cultivars, such as, DNA-based restriction fragment length polymorphisms (RFLPs) (Crowhurst *et al.*, 1990), microsatellites, or simple sequence repeats (SSRs) (Crowhurst and Gardner, 1991), polymerase chain reaction (PCR)-amplified chloroplast DNA fragments (Cipriani and Morgante, 1993; Cipriani, 1994; Cipriani *et al.*, 1998), and isoenzymes (Messina *et al.*, 1992; Testolin and Ferguson, 1997).

1.2.2 Sex identification

Identification of male and female genotypes and cultivars within the species is the first step toward the correct classification of kiwifruit germplasm. *A. chinensis*, a diploid species, is the progenitor of *A. deliciosa* var. *deliciosa*, which is a hexaploid, $2n = 6x = 174$, and the chromosomes X and Y are not morphologically distinguishable due to their small size (McNeilage, 1997). It is important to identify the sex of the plants at juvenile stage in order to raise material as male and female plant populations before planting an orchard for breeding purposes. The PCR-based random amplified polymorphic DNA (RAPD) technique can be used to identify the dioecy in several species. The breeding programs aimed at selection for fruit characteristics could gain an advantage from molecular sex markers for identifying male seedlings and discarding them at the early stages of growth.

After the early work of Hirsch and Fortune (1984) who used peroxidase for sex determination in *Actinidia*, research in this area has continued with some modifications (Hirsch *et al.*, 1992, 1997) and is further extended to the isoperoxidase, isopolyphenyl oxidase (Auxtova *et al.*, 1994), and polyamines (Biasi *et al.*, 1999). Since this technique

has certain limitations, more attention is being focused on molecular markers.

Cipriani *et al.* (1996) found that none of the 80 RAPD primers (10 bp) tested produced bands linked to the sex. Fraser *et al.* (1997) constructed cDNA libraries from female and male buds of a sibling family of *A. chinensis* at pollen pre- and postmeiotic stage, and found one clone showing high sequence homology to the *fil 1* protein expressed in anther filaments of snapdragon. Harvey *et al.* (1997a, b) used sex-linked RAPD markers (800 bp) and found that sex-determining genes are located in a pair of chromosomes functioning like XX/XY system with male heterogamety. By using amplified fragment length polymorphism (AFLP)-based bulked segregant analysis and then individual analysis of a sibling family of diploid *A. chinensis*, Zhang *et al.* (1998a) observed one male-exclusive and one female-exclusive band.

Besides sex labeling, RAPDs have also been used in cultivar typing: 20 primers were selected for producing polymorphic fragments in 13 kiwifruit cultivars (Cipriani *et al.*, 1996, 1997), and parentage analysis as well as ploidy level of crosses between *A. deliciosa* and *Actinidia arguta* was studied by using flow cytometry and RAPD markers. The results showed the existence of 5x and 2x progenies from 4x and 6x crosses (Chat and Dumoulin, 1997).

Shirkot *et al.* (2002) identified eight sex-linked markers and from seven cultivars of *A. deliciosa* studied, six were female specific and two were male specific in nature.

1.2.3 Mapping

In *A. chinensis*, Weising *et al.* (1996) identified a set of microsatellite markers from a small insert genomic library of DNA, and designed 18 primer pairs according to the DNA sequence of 35 hybridizing clones. Using most of these primer pairs, they successfully fingerprinted a range of closely related varieties in *A. deliciosa*. Huang *et al.* (1998) isolated and sequenced 263 microsatellites-containing clones from *A. chinensis*, with a high degree of polymorphism. These microsatellites were used to support the hypothesis that original diploid species of *Actinidia* were polyploids with

a basic chromosome number $x = 14/15$. A wide range of genetic similarity was observed by using RAPD markers among the 40 taxa, while for varieties of the same species it was 0.54 and for different species it was 0.28. Although the phylogenetic analysis revealed a clear indication that section *Leiocarpace* was a monophyletic group, the subdivision of the other three traditional sections was poorly supported. The majority of the species clustered into geographic subgroups in accordance with their natural distribution (the Yangtze River, Southeastern China, Southern China, and Southwestern China). The intrageneric subdivisions of *Actinidia* appeared to be difficult, but some subdivisions could be explained by the geographic distribution of the species, particularly for species of Liang's sections of *Maculatae* and *Stellatae* (Huang *et al.*, 2002).

Maps were constructed from enriched genomic libraries together with AFLP markers using interspecific crosses between *A. chinensis* and *A. callosa* (Testolin *et al.*, 2001). Later, Frase *et al.* (2004) used microsatellites from expressed sequence tags (ESTs) to evaluate the frequency of occurrence and the level of polymorphism in genetic map construction. They found that EST-derived microsatellites of *A. chinensis* gave large number of possible markers highly polymorphic between the parents and allowed the construction of a map. These results showed that EST libraries are a valuable resource for the supply of markers for genetic mapping of *Actinidia*.

Crowhurst and Gardner (1991) suggested for the first time that kiwifruit may be an allopolyploid species because they found genome-specific repeat sequences in *A. deliciosa*. In addition, 26 restriction sites from five PCR-amplified chloroplast sequences were mapped and analyzed. Three species out of the 20 examined originated through natural interspecific hybridization. *In situ* hybridization with the species-specific repeat sequence has been carried out by Yan *et al.* (1997b), who observed six hybridization sites in some accessions of *A. chinensis*, and all of *A. deliciosa*. These results indicated that the genomes of polyploid *Actinidia* are similar but not identical. The molecular data clearly showed that some taxa, such as *Actinidia rufa* and *Actinidia kolomikta*, occupy a wrong taxonomical position (Cipriani *et al.*, 1998).

The efficiency of two molecular markers (RAPD and SSR) has been compared for investigating the

clonal stability of micropropagated kiwifruit genotypes with interesting agronomic traits maintained in collection. Both molecular marker techniques were able to amplify all of the genotypes, but only SSR markers could detect genetic variation induced in micropropagated plants of cv. Tomuri. (Palombi and Damiano, 2002).

1.3 Economic Importance

In China, most of the orchards are planted with *A. chinensis* accessions (Huang *et al.*, 1999) whereas the world market is based almost exclusively on the pistillate cultivar Hayward, with two pollinators, Matua and Tomuri, selected from *A. deliciosa* by scientists of New Zealand who imported this species around 1930 from China. In this country, the cultivation became economically important from the mid 1960s, and only in early 1970s this species became widely distributed, with little attention to the attitude toward the environment. The other pistillate cultivars like "Abbott", "Allison", and "Bruno", were cultivated together with "Hayward" and they lost their popularity in favor of "Hayward" for its better shape, size, and long storage ability. However, this cultivar is not free from defects, which include high risk of sudden disease occurrence, pest infection or frost damage for its very narrow genetic base, and the dioecism character typical of the genus.

In the recent years, few accessions from cv. Hayward have been selected among the offspring of *in vivo* crosses and from somaclonal variation derived from micropropagated plants. They included hairless fruit, and early fruit ripening, comprising the accession Summer 4605[®] and Summer 3373[®] having 35 and 50 days, respectively earlier ripening than cv. Hayward (Ossani, 1994; Summerkiwi[®] 20010160 and 20010159 patented by V. Ossani from the Istituto Sperimentale di Frutticoltura, Rome (Del Pane, 2005)). Accessions with hairless fruit are susceptible to fruit fly (*Ceratitis capitata*) and for this reason they have not been included in the cultivation.

Recently, the New Zealand cultivar "Zesprigold" (Hort16A) obtained from *A. chinensis*, presents interesting characteristics such as, yellow pulp, higher vitamin C content, sweet flavor, and contemporary ripening to Hayward. The cultivar also has some negative attributes such

as, early blossom and shooting, its fruits are almost hairless and have a mucro that can damage the other fruits during handling. Suitable pollinators used for this cultivar are “K2” and “K3”.

Only few other species with different ploidy levels but with a base chromosome number of 29, seem to be important from an economical point of view, such as: *A. chinensis* ($2n = 2x = 58$), *A. deliciosa* ($2n = 6x = 174$), *A. deliciosa* var. *chlorocarpa* ($2n = 2x = 174$), var. *coloris* ($2n = 6x = 174$), *A. glaucophylla* ($2n = 2x = 58$), *A. guilinensis* ($2n = 2x = 58$), *A. indochinensis* ($2n = 2x = 58$), *A. setosa* ($2n = 2x = 58$), *A. arguta* ($2n = 4x = 116$), *A. arguta* var. *purpurea* ($2n = 8x = 232$), *A. eriantha* ($2n = ?x = 58$), *A. latifolia* ($2n = 2x = 58$), *A. chrysantha* ($2n = 4x = 116$), *A. melanandra* ($2n = 4x = 116$), *A. kolomikta* ($2n = 2x = 58$), and *A. polygama* ($2n = 2x = 58$) (Den and Sen, 1986; Xiong and Huang, 1988; McNeilage and Considine, 1989; Watanabe *et al.*, 1990; Yan *et al.*, 1997a).

1.4 Production, Nutritional Attributes, and Industrial Uses

Kiwifruit has gained enormous popularity in many countries of the world due to its nutritional and medicinal values. World production has increased from the 875 727 metric tons in 1998 to 1 120 938 metric tons during 2005 covering a higher cultivated area of 68 542 ha compared to 52 972 ha of 1998. This includes only four countries as the main producers: Italy (415 052 metric tons), China (340 000 metric tons), New Zealand (318 000 metric tons), and Chile (150 000 metric tons) (Huang and Ferguson, 2003; FAOSTAT, 2006). Only in China about one-quarter of total cultivated areas produced 11 cultivars of *A. chinensis*, the remainder area with 11 cultivars of *A. deliciosa*.

The beneficial effects of an increased consumption of fruit and vegetables against oxidative DNA damage of human cells have been attributed and demonstrated, under *ex vivo* and *in vitro* conditions, to the various antioxidants present in some foods (Collins *et al.*, 2001). The main antioxidant is the vitamin C or L-ascorbic acid and its partially oxidized form: the L-dehydroascorbic acid (DHAA). Kiwifruit, as well as the genus *Citrus* and the guava (*Psidium guajava*) are excellent

sources of vitamin C. The genus *Actinidia* presents large differences in fruit composition among species and often within cultivars (Beever and Hopkirk, 1990; Ferguson, 1990a, 1991; Ferguson, 1990b; Ferguson and MacRae, 1992). There are a considerable number of cultivars and selections in the genus with a wide diversity in size and shape of fruit, hairiness, color of flesh, actinidin content, flavor and taste (Ferguson, 1991; Boyes *et al.*, 1997), and wide variation in vitamin C content (Ferguson and MacRae, 1991). The cultivar Hort16A of *A. chinensis* contains 50% higher vitamin C than the cultivar Hayward (80–120 mg per 100 g fresh weight), and the cv. Sanuki Gold reach more than threefold that of Hayward, as well as cv. Gassan, Issai, and Mitsuko (Nishiyama *et al.*, 2004b), while within the species *A. deliciosa* the range goes from 30 to 400 mg per 100 g of fresh weight. High concentration of ascorbic acid are also reported in *A. arguta* (40–185 mg), *A. chinensis* (up to 180 mg) (<http://www.naturalhub.com>; Chen and Chen, 1998; Muggleston *et al.*, 1998), and the ratio of L-ascorbic acid to total ascorbic acid tend to be higher than that of other species (Nishiyama *et al.*, 2004a): *A. chrysantha* (around 70 mg), and *A. polygama* with very high levels in *A. eriantha* and *A. latifolia* (over 1000 mg per 100 g of pulp) (Ferguson, 1991), and *A. kolomikta* (Kola and Pavelka, 1988). On the other hand, phenols contents and total antioxidant activity of *A. chinensis* rated the second lowest after plum (Imeh and Khokhar, 2002). Like many other fruits, it has low vitamin B and carotene contents. Minerals are also high, especially potassium and magnesium as well as copper, zinc, and manganese. These cations are important for regulating acid/base ratio in the organism, increasing the alkaline reserve in the blood and increasing the pH of the urine (Panatta, 1990).

A negative aspect is that it contains oxalates, which is considered to be a breakdown product of ascorbic acid (Keates *et al.*, 2000; Kostman *et al.*, 2001), and it has adverse nutritional effects because it binds Ca^{2+} , Mg^{2+} , and Fe^{2+} and lowers their availability in the diet by decreasing their absorption, as well as calcium oxalate crystallization and kidney stone formation (Hodgkinson, 1981; Noonan and Savage, 1999). Furthermore, it was found that the needlelike calcium oxalate crystals found in kiwifruit can irritate the mucous membranes of the mouth

(Perera *et al.*, 1990; Walker and Prescott, 2003). Recently, the ascorbic acid and total oxalate were measured in fruit from six genotypes of *A. chinensis*: the whole fruit mean ascorbic acid ranged from 98 to 163 mg per 100 mg of fresh weight, whereas mean oxalate varied between 18 and 45 mg. Ascorbic acid was highest in the inner and outer pericarp while was absent in the seeds. Oxalate was concentrated in the skin, inner pericarp, and seed, but both substances are not concomitants. It may be possible to select cultivars for high vitamin C content without having high levels of oxalate (Rassam and Laing, 2005).

Kiwifruit is involved in allergic reactions causing local or systemic mucosal or both types of symptoms by an IgE-mediated mechanism (Fine, 1981). This immunoglobuline corresponds at a 30 kD protein, the major allergen and the main protein in kiwifruit, it is called actinidin or Act c 1, a proteolytic enzyme belonging to the class of thiol-proteases, a cysteine protease (Pastorello *et al.*, 1998). Researches have demonstrated that there is a difference in actinidin content within the species and cultivars: in the cvs. Sanuki Gold, Ananasnaya, Shinzan, Hirano, Gassan, and Mitsuko, both actinidin concentration and protease activity were much higher than in cv. Hayward, while cultivars First Emperor, Tear drop, Kosui, Awaji, Nagano, and Kosen were lower than Hayward. The allergen is also present in fruits of the newly released cultivar Zespri™ Gold of *A. chinensis* (Lucas *et al.*, 2005). Regarding allergens content within the species, in fruits of *A. arguta* was much higher than in *A. deliciosa* or *A. chinensis* fruits (Nishiyama *et al.*, 2004a, b; Yamanaka *et al.*, 2004). Subsequently, Gavrovic-Jankulovic *et al.* (2005) found that the quality and quantity of allergen content vary in function of the time of fruit harvesting or fruit ripening of *A. deliciosa*: in November harvest it was found the highest allergenic potential of Act c 1 and Act c 2 in fruit extracts. The potential allergenic effect of *A. arguta*, known as hardy kiwifruit, has also been studied by Chen *et al.* (2006) as raw fruit and processed food product. They found that the heat processing alters allergenic protein structure, reduces *in vitro* IgE binding, and reduces the risk of eliciting an allergenic response in those with allergies to raw kiwifruit.

In the ancient Chinese medicine, kiwifruit has been used as therapy for different kinds of cancer. Motohashi *et al.* (2002) studied the anticancer

activity of kiwi extracts of commercial cultivar Hort 16 (Gold) and found that many extracts switches from pro-oxidant action to antioxidant action depending on its concentration and they showed also tumor selectivity, cytotoxic, and antimicrobial activity.

Market acceptance relates to kiwi fruit color, fruit size, texture of flesh, eating quality, price, availability and continuity of supply. Fruit size is one of the most critical parameters in the selection of kiwi. Fruit weight must be superior to 100 g with shape typical of cv. Hayward, dark brown skin. Kiwi plants often require treatment by bioregulators such as the cytokinin-like compound N-(2-chloro-4-puridil-N-phenylurea) (CPPU) (Lewis *et al.*, 1996) and hydrogen cyanamide to enhance fruit size. The hairless skin seems to be more acceptable to consumers. Another important character is pulp color that ideally should be bright green; other colors are not fully acceptable, probably for the absence of bright colors. Fruit flavor is another important criterion in selecting kiwi cultivars and depends on the balance between acidity and sweetness. Fruits of *A. chinensis* are characterized by higher sugar content and better smell than *A. deliciosa*. Furthermore, this species presents a longer harvesting period, from September to November in Northern China (Ferguson, 1984). The newly released cv. Zespri™ Gold (*A. chinensis*) has only been exported from New Zealand since 1998 and then to the United States and Europe in 2000, and its consumption is increasing in many parts of the world. New kiwifruit cultivars from *A. arguta*, known as “baby kiwi”, are also been produced in the United States, Europe, New Zealand, and South America due to the wonderful flavor, good productivity, fruit size, extended maturity dates, good storage and shelf life (Williams *et al.*, 2003).

Fruits are consumed mainly as fresh within 1–6 months after harvesting. A small amount of the total production is used for food industry, such as jams, juices, and syrups. In New Zealand, the residue after processing is used to produce wine (Monastra, 1991).

1.5 Traditional Breeding: Achievements and Limitations

Although the large variability of traits is found in the vast genetic resources within the genus

Actinidia, many interesting agronomic characters are not present in the commercial cultivars such as drought tolerance, adaptation to cool climates, or disease resistance. Interspecific crosses may be carried out, or interesting genes could be identified and transferred to cultivated kiwi. Unfortunately, the genetic improvement by traditional cross-breeding and the potential of *Actinidia* germplasm remains underexploited due to the dioecism of the genus, the unknown genetic background of staminate plants, the relative long juvenile phase, and the presence of at least one-half of staminate plants among the offspring, which increases the cost and time for genetic selection with traditional breeding. Furthermore, the different levels of ploidy among the *Actinidia* species represent another obstacle for interspecific hybridization; so many attempts to produce plantlets between species failed (Pringle, 1986; McNeilage and Considine, 1989; Mu *et al.*, 1990b; Ke *et al.*, 1991). To overcome these difficulties different biotechnological methods, such as protoplast culture, somatic hybridization, embryo rescue, creation of dihaploids lines have been developed.

1.5.1 Protoplast culture

Since the first report on protoplast isolation in the cv. Hayward by Cossio and Marino (1983) several protocols have been described. In some cases only small colonies were formed (Pedroso *et al.*, 1988; Revilla and Power, 1988), while successful results were reached in shoot regeneration from leaf callus and cotyledon protoplasts of *A. chinensis* (Mii and Ohashi, 1988; Tsai, 1988; Xiao *et al.*, 1992). Plant regeneration from protoplasts obtained from preserved callus, leaf and/or cotyledon have been also carried out in *A. deliciosa* (Oliveira and Pais, 1991, 1992; Cai *et al.*, 1992; Xiao *et al.*, 1993). Somaclonal variation on leaf shape and plant morphology was observed as well as variation in the chromosome number (Cai *et al.*, 1992). Protoplasts from different *Actinidia* species were successfully isolated and cultured in *A. arguta* var. *arguta*, var. *purpurea*, cv. Issai, *A. chinensis*, *A. kolomikta*, *A. polygama*, and *A. eriantha* and many plants were obtained (Derambure and Hirsch, 1995; Zhang *et al.*, 1995; Xiao and Hirsch, 1996, 1997). From the regenerated plants of *A. eriantha*, obtained by Zhang *et al.* (1995), changes in chromosome number and ploidy level were found

as well as the multinucleate phenomenon of the cells in most of the plants under study (Zhang *et al.*, 1997, 1998b).

A purification method to obtain populations of leaf protoplasts of Hayward was also developed and the efficiency of β -glucuronidase (GUS) reporter gene expression was compared by direct DNA transfer and plant regeneration (Raquel and Oliveira, 1996).

The first efforts on protoplast fusion were carried out by Xiao and Han (1997) who worked with protoplast from *A. chinensis* var. *chinensis*, *A. deliciosa* var. *deliciosa*, and *A. kolomikta*. Successful results were obtained from both interspecific crosses and RAPD analysis indicated that five clones had RAPD banding patterns corresponding to the parental bandings, and the ploidy level was also changed.

1.5.2 Somatic hybridization

In order to avoid frost damage before harvesting, new cultivars with earlier ripening or frost resistance are recommended in genetic improvement programs. *A. chinensis* could supply valuable genes for crossing in order to obtain earlier harvesting genotype (Testolin *et al.*, 1996). Interspecific somatic hybrids between *A. chinensis* and *A. kolomikta* have been obtained by protoplast fusion: the chilling tolerance under *in vitro* conditions was similar to *A. kolomikta*. The expected cold resistance might be higher than *A. chinensis* plants (Xiao *et al.*, 2004).

1.5.3 Embryo rescue

The first efforts to produce interspecific hybrid with successful results were obtained by Mu *et al.* (1990a) who worked with *A. chinensis* and *A. melanandra*, and the conditions for successfully rescuing embryo were determined by Mu *et al.* Some plantlets were generated, and most of them grew slowly, lacked apical dominance, and did not survive in the greenhouse. The crosses were repeated later and the characteristics of the plants were studied (Harvey *et al.*, 1995). In order to study embryo and endosperm development of the seeds Xi-jin *et al.* (1992) produced hybrids between *A. deliciosa*, *A. eriantha*, and *A. arguta*. Some incompatibility was observed but normal seedlings were produced from embryos of normal

appearance. Further efforts to improve the embryo rescue technique and in order to assess the degree of crossability occurring in the genus *Actinidia*, a set of culture media and techniques were developed to ensure the survival of the embryos at globular and heart stages. In several crosses, embryos at torpedo stage were rescued when incubated in appropriate medium. The embryo rescue was the unique tool that led to hybrid plantlets for four crosses between *A. kolomikta* × *A. chinensis*, *A. polygama* × *A. valvata*, *A. arguta* Issa × *A. polygama*, and *A. kolomikta* × *A. deliciosa*, which permit to deduce the wide interspecific crossability between different sections based on traditional taxonomy (Hirsch *et al.*, 2001).

1.5.4 Homozygous lines

In conventional breeding programs, a pure line or haploidization is developed after several generation of self-pollination, which is not possible to carry out in fruit crops because of their long reproductive cycle, high degree of heterozygosity, and self-incompatibility. The interest of using haploids and doubled haploids lies in the possibility of shortening the time needed to produce homozygous lines compared to conventional breeding. Haplo-diploidization through gametic embryogenesis allows single-step development of complete homozygous lines from heterozygous parents. Embryogenesis and organogenesis were achieved from callus tissue of anthers of *A. chinensis* var. *chinensis* and *A. deliciosa* var. *deliciosa* by Fraser and Harvey (1986) who found that the embryogenic potential was dependent on genotype and sex of plant.

To facilitate the crossing among diploid, tetraploid, and hexaploid and to improve fertility in some hybrids, encouraging results of ploidy manipulation have been obtained by Fraser *et al.* (1991) who tried to double the chromosome number via callus from stems of *A. chinensis* and pollen of *A. deliciosa*. A combination of colchicine treatment and tissue culture regeneration produced tetraploids plants from diploids *A. chinensis* var. *chinensis*. They found also that endosperm culture gave rise mixoploidy plants, but continued culture and regeneration led to the stabilization of chromosome number. The use of oryzaline treatment in one parthenocarpic trihaploid from cv. Hayward was more effective than colchicine in producing

hexaploid and didecaploid plants (Chalak and Legave, 1996). Rugini *et al.* (1996a) observed an increase in ploidy level among regenerated plants from callus in both staminate and pistillate cultivars without the use of chemical treatments. After 14 years of their establishment in the experimental field they have not bloom yet although they present a mature morphological aspect.

1.5.5 Selective pressure and somaclonal variation

Another strategy for inducing genetic variability is manipulating the substrate composition in order to create conditions for a selective pressure. Marino and Battistini (1990) produced somaclones tolerant to high pH under *in vitro* conditions by culturing the *in vitro* explants in media with high pH. Muleo *et al.* (1996) cultured calli in high concentration of glucoselike synthetic compounds: 3-O-Methylglucose and N-Methyl-D-glucamine. Both compounds induced a similar type of genetic variation in regenerated plants, contrary to NaCl at the same water potential. RAPD analysis showed different frequencies and patterns of polymorphic fragments. Although interesting results have been obtained by this technique, it produces some undesirable traits, which do not have agronomic importance. Somaclonal variation for active limestone tolerance has also been obtained by Marino and Bertazza (1996) in *A. deliciosa* from somaclones previously obtained with tolerance to high pH (Marino and Battistini, 1990). Recently, Caboni *et al.* (2003) induced somaclonal variation by *in vitro* organogenesis under selective pressure with high NaCl concentrations, obtaining five tolerant shoot lines of the cv. Tomuri, and RAPD analyses showed polymorphism in two of them. Later, the different responses of the selected clone to salt stress conditions were confirmed from field trial.

The ability to regenerate plants from callus encouraged scientists to induce somaclonal variation for enhancing the ploidy level, increase the fruit size, calcareous, and drought tolerance. Somaclonal variation has been observed in different tissues of *Actinidia* after *in vitro* culture. Hirsch *et al.* (1992) studied the occurrence of variation by culturing different explants such as stem, leaf, root, ovary, anther filament,

mature endosperm, and embryos from *in vitro* regenerated plantlets. Gui *et al.* (1993) reported that endosperm-derived plants had different fruit size and shape, seed number, and chromosome variation (from 58 to 146). Mostly plants were aneuploids with only a few triploids but none of them were parthenocarpic.

1.5.6 Parthenocarpy

Parthenogenesis in *A. deliciosa* was obtained by Padey *et al.* (1990) by using lethally irradiated pollen, and also the parthenogenic response was investigated for Hayward where high rates of trihaploids were detected as well as some hexaploids by spontaneous doubling (Chalak and Legave, 1997). Later, studies on the endosperm development after pollination with irradiated pollen from different male cultivars gave rise that endosperm was autonomous and represent the $2n$ level and 30% of the ovules developed (Musial and Przywara, 1998, 1999).

2. DEVELOPEMENT OF TRANSGENIC KIWIFRUIT

In the last two decades, transgenic plants of *A. deliciosa* have been recovered with some foreign genes of interest: *rolABC*, *rolB*, whole T-DNA, *osmotin*, human epidermal growth factor (*hEGF*). Research on transgenics in *Actinidia* started when Rugini *et al.* (1989) reported genetic transformation and plant regeneration from leaf discs of *A. deliciosa* with the *rol* genes of *Agrobacterium rhizogenes*. Transformation experiments were also tried with *A. rhizogenes* by González *et al.* (1990), and Atkinson *et al.* (1990) with *Agrobacterium tumefaciens* under glasshouse conditions. Subsequently, both direct and indirect gene transfer methods have successfully being tried in three species of the *Actinidia* genus by using protoplasts and different explants of zygotic and maternal origin.

Rugini and Mariotti (1992) developed a procedure to regenerate transgenic plants for most of the genes of the T-DNA of *A. rhizogenes*. Tissues (leaves and shoots) produced abundant hairy roots in auxin-free medium after the co-cultivation with both *A. rhizogenes* wild type

and *A. tumefaciens* carrying *rolABC*, and *rolB* genes, and the selectable marker gene neomycin phosphotransferase II (*nptII*). With *A. tumefaciens* LBA4404 carrying the *rolB*, alone or associated with *A* and *C*, of *A. rhizogenes*, the roots emerged from the inoculation point or at the base of the shoots. Molecular analysis of these roots indicated that a few of them were transgenic probably due to inductive effect of transgenic cells on the nontransgenic neighboring cells. In addition for *rolABC* or for *rolB*, roots still attached to the shoots grew very fast for several days even at high kanamycin concentrations (500–1000 mg l⁻¹). Selection could be possible with detached roots on hormone-free medium, before placing them on medium for regeneration of transgenic shoots.

2.1 Growth Habit Modifications

Modification of the pattern of growth habit may permit labor saving in kiwifruit vineyard management and reduce the cost of production.

The first efforts to obtain *Actinidia* plants with altered phenotype were reported by Rugini *et al.* (1989, 1990, 1991) on the male late-flowering pollinator called “GTH”, which was transformed with the *rolABC* genes of *A. rhizogenes*, cloned in pBin19 and transferred into *A. tumefaciens* strain LBA4404. Transgenic plants, regenerated from leaf disc callus, showed the typical hairy root phenotype as described in herbaceous species (Tepfer, 1984). Furthermore, leaf discs or 3- to 4-node leafy microcuttings of these transgenic plants showed an increased ability to produce roots in auxin-free medium. Subsequently, following the same transformation technique, transgenic plants for *rolABC* and *rolB* were regenerated from the cv. Hayward (Rugini and Mariotti, 1992). Field evaluation of male and female transgenic cultivar is underway since 1998 (Rugini *et al.*, 1999). Firsov and Dolgov (1997) regenerated transgenic plants of *A. kolomikta* having *rolC* gene; all transgenic plants for *rolC*, singly or associated with other genes, showed the morphological dwarf characteristic typical of plants transformed by *rolC*.

Transformation by using the whole T-DNA of *A. rhizogenes* was performed by Yazawa *et al.* (1995) who obtained transgenic plants with “hairy root” phenotype from roots induced by *A. rhizogenes* NIAES 1724 in hypocotyls

of *A. deliciosa* seedlings. A new *A. rhizogenes*-mediated transformation protocol was developed by Yamakawa *et al.* (1996) who obtained direct bud formation on petioles of leaf explants of cvs. Hayward, Abbott, Matua, and Bruno infected by Japanese wild strains of *A. rhizogenes* (ArM 123, IFO14555, A5, and A13).

The controlling mechanism of plant morphogenesis is one of the most important questions in plant biology. Plant homeobox genes are thought to control plant morphogenesis through the regulation of expression of genes involved in plant development. To elucidate the mechanisms of plant morphogenesis, genetic transformation with a synthetic gene encoding the *hEGF* under the control of cauliflower mosaic virus (CaMV) 35S promoter has been done for the first time to produce human bioactive peptides in plants. Young leaves of the regenerated transgenic plants of *A. chinensis* expressed the highest hEGF peptide content, 65 pg mg⁻¹ soluble protein (Kobayashi *et al.*, 1996). Plant growth was also modified by using the rice gene *OSH1*, which contains a homeobox whose product is thought to have DNA binding activity. Kusaba *et al.* (1999) transformed *A. deliciosa* with the rice homeobox containing *OSH1* gene under the control of three different promoters. Only the transgenic plants containing the *OSH1* cDNA under the control of the 35S promoter showed morphological changes such as dissected leaf margin, dwarfism, and loss of apical dominance. Transgenic kiwifruit plants overexpressing *OSH1* showed a suppression of the gibberellin GA20 oxidase activity, while applications of gibberellin (GA) could not completely recover plant morphology and protein profiles. Furthermore, studies on protein content indicated wide range alterations at protein level and protein accumulation (Kita *et al.*, 2006).

2.2 Fungal and Bacterial Resistance

The *osmotin* gene, normally expressed under the stress conditions (Liu *et al.*, 1994; Zhu *et al.*, 1996), was introduced by *A. tumefaciens* strain LBA4404 with plasmid pKYLX71 carrying tobacco *osmotin* gene and *nptII* gene under 35S promoter into leaf discs and petioles of *in vitro*-grown shoots of the cv. Hayward. Regenerated shoots showed deformed leaf lamina, chimerism,

and also spots lacking chlorophyll under *in vitro* conditions; however, each apparent morphological modification disappeared in potted plants as well in the field (Rugini *et al.*, 1999). Another gene used to induce disease tolerance was tried by Nakamura *et al.* (1999), which transformed leaves, petioles, and stem segments of the cv. Hayward with the soybean β -1,3-endoglucanase cDNA under the control of CaMV promoter with *A. tumefaciens* strain LBA4404 harboring a binary vector pROK1a-EG. Young leaves of regenerated plants showed an increase enzymatic activity in many transformants, which reduced the attack of *Botrytis cinerea*. Whereas Kobayashi *et al.* (2000) did not obtain resistant plants of the cv. Hayward to *B. cinerea* after transformation experiments with the *stilbene synthase* gene from *Vitis* spp., but the fruits contained high amount of piceid, which is beneficial on human health.

Regarding bacterial diseases, Balestra *et al.* (2001) investigated the sensitivity of transgenic tissues to *rolABC* genes; how cytokinins and auxins could modify the susceptibility to *Pseudomonas viridiflava* and *P. syringae* pv. *syringae* whether the susceptibility was expressed in the offspring. The staminate cultivar showed high resistance to both pathogens, while the pistillate cultivar resulted to be highly susceptible. Furthermore, the offspring derived from the cross between transgenic staminate cultivar and the pistillate cultivar resulted in susceptible, probably due to the high nitrogen content in the leaves of *rolABC* plants. High resistance to *P. viridiflava* was obtained in those offspring plants lacking the *rolABC* genes. In fact, leaves resulted were tender and greener than those of the nontransgenic plants, except in one genotype, which resulted to have the same level of resistance than staminate plants.

2.3 *Gus*, *cat*, and *nptII* Reporter Genes

In most of the transformation experiments marker genes have been used to optimize the parameters of co-cultivation, culture media, explants, and *in vitro*-grown conditions for developing efficient transformation protocols in morphogenic tissues and protoplasts.

Chloramphenicol acetyltransferase (*cat*) gene has been used by Oliveira *et al.* (1991) to assess the conditions for polyethylene glycol

(PEG)-mediated transfection of kiwifruit protoplasts. Transient expression of *cat* gene was observed in protoplasts of the cv. Harward by using 30% PEG 4000 and by submitting protoplasts to heat shock (45°C, 5 min) prior to transfection. Further research showed a reduction in transient expression rates of either the *cat* or the *gus* genes when electroporation was tried without reproducing plasmid uptake (Oliveira *et al.*, 1994). Raquel and Oliveira (1996) continued to study the transient expression of the *gus* gene in two protoplast populations obtained from *in vitro*-grown leaf material of the same cultivar. One population consisted of hyaline or light green protoplasts originating from epidermis and leaf veins, and the other consisted of green protoplasts very dense in chloroplasts and originating from mesophyll. Transient expression and regeneration ability was more efficient in those from the former population, particularly when subjected to heat shock prior to transfection.

Uematsu *et al.* (1991) successfully introduced *nptII* and *gus* genes into hypocotyls and stem segments of *A. deliciosa* after co-cultivation with a disarmed succinamopine strain of *A. tumefaciens* EHA 101 (derivative of A281), harboring the binary vector pLAN411 or pLAN421 under the control of CaMV 35S or the *nos* promoter. Janssen and Gardner (1993) developed an *Agrobacterium*-mediated gene transfer system with transient GUS expression by comparing several *Agrobacterium* strains, binary vectors, and health of the explant of the same cultivar. Stable kanamycin resistant transgenic plants were obtained at high frequency from the optimized systems. Oliveira *et al.* (1994) also compared the transformation efficiency of explants of stem, petiole, and root, from *in vitro*-grown plantlets of the cv. Hayward. Explants were co-cultivated with *A. tumefaciens* strain LBA4404 carrying p35SGUSINT for 48 h. Some green calli could be recovered from stem and petiole explants under low kanamycin concentration and some adventitious shoots expressed *NPTII* activity.

Fraser *et al.* (1995) compared the amenability of transformation and regeneration procedures of *A. chinensis* and *A. deliciosa* by using the *A. tumefaciens* strains A281 and C58, both carrying the binary vector pKIWI105. During regeneration, shoot initiation from *A. chinensis* was more rapid and prolific than *A. deliciosa*, although *A. chinensis* was more sensitive to

little changes in growth regulator concentration. Comparisons between the different genotypes of *A. chinensis* showed only minor differences in growth regulator preferences. In *A. kolomikta*, an efficient regeneration and genetic transformation method has also been developed by Firsov and Dolgov (1997) with leaf explants co-cultivated with several *A. tumefaciens* strains. Selection of transformants was carried out under high concentrations of kanamycin and hygromycin. Good *gus* expression was observed in a high number of transgenic regenerants. Recently, *gus* activity and molecular evidence for incorporation of the gene was observed in leaf, stem, root, petal, and fruit tissues in transgenic *A. eriantha* plants after two years of transformation experiments (Wang *et al.*, 2006).

2.4 Methods of Gene Transfer

Some procedures are commonly used for transferring genes into the plant cells such as microbe-vectored systems (*Agrobacterium* mediated and virus mediated), artificial delivery system (DNA uptake by diffusion, membrane diffusion, electroporation, laser microbeam, microinjection, and microprojectiles), and natural delivery system (pollen tube pathway and floral tillers) (Dandekar, 1992). In *Actinidia*, both *Agrobacterium*-mediation and protoplast up-take system methods have been used for genetic transformation.

2.4.1 *Agrobacterium*-mediated gene transfer

The development of an efficient *Agrobacterium*-mediated transformation system is a prerequisite for functional genomics studies and for delivery of novel genes into established cultivars. Most of the reports on transformation and isolation of transgenic plants in *Actinidia* have involved *Agrobacterium*-mediated gene. This is affected by the transfer of a segment of the Ti or Ri plasmid known as T-DNA into the nuclear genome of the plant (Chilton *et al.*, 1982). According to Janssen and Gardner (1993) four factors affect transformation frequency: healthy and actively growing source tissue; the ability of *Agrobacterium* to efficiently transform cells; the bacterial strains; and the binary vector used strongly influence the

frequency of transformation. They found that A281 *A. tumefaciens* strain was the most efficient for transformation; the presence of a layer of moistened filter paper between the leaf explants and the co-culture media, and; the presence of 20 μ M acetosyringone in both bacterial culture media and the co-culture media.

The most commonly used strains of *A. tumefaciens* are LBA4404, A281, EHA101, C58, GV3101; and for *A. rhizogenes* the most commonly used strains are NCPPB 1855, NIAES 1724 ArM 123, IFO 14555, A5, A13, and G746. It is important to consider other factors that could affect transformation efficiency such as: (a) co-cultivation period variability (from 24 to 36 h); (b) use of scratching agents during the co-cultivation of the explants with *Agrobacterium*, such as carborundum granules (Rugini *et al.*, 1991); and (c) addition of antibiotics such as cefotaxime or carbenicillin, to the regeneration medium for inhibiting bacterial growth. Carbenicillin is commonly used since this antibiotic does not affect the regeneration process in kiwi.

2.4.2 Artificial delivery systems

The most promising delivery systems used in *Actinidia* is DNA uptake by diffusion using PEG-mediated transfection and electroporation (Oliveira *et al.*, 1991; Raquel and Oliveira, 1996). Electroporation involves the formation of transient pores in biological membranes by the discharge of altering electrical current. This is suitable to species not susceptible to *Agrobacterium* infection (Gupta *et al.*, 1988). The use of protoplasts in these systems is necessary, since they have an exposed plasmalemma, thereby highly efficient plant regeneration protocols are necessary.

2.5 Selection of Transformed Tissue

After the introduction and integration of alien genes into plant cells, only the transformed cells should divide and subsequently differentiate into either shoots or embryos. In order to select transformed cells a selectable marker is included together with the gene of interest. The *nptII* gene, encoding resistance to the antibiotic kanamycin, has been widely used in transformation

experiments, both in herbaceous and in woody plants (Dandekar *et al.*, 1993). This gene is able to inactivate also other aminoglycoside antibiotics such as paromomycin, neomycin, and geneticin rather than kanamycin (Yoshikura, 1989). Efficient selection of the transformed cells is usually carried out with kanamycin at concentration from 20 to 100 mg l^{-1} depending on the explant. Suitable concentration of kanamycin and the time to apply the selective pressure must be initially determined for each kind of tissue of the genotype to prevent regeneration from untransformed cells and at the same time to avoid inhibition of cell division and differentiation of transformed cells. In some other transformation experiments, *cat* gene was used, as a reporter gene, to assess the conditions for PEG-mediated transfection in protoplasts (Oliveira *et al.*, 1991).

Several studies have been conducted to determine the optimal conditions for the selection of transgenic cells after co-cultivation with *Agrobacterium*: Rugini *et al.* (1991) found that untransformed callus and apical shoots stopped growing in a medium containing 20 mg l^{-1} of kanamycin. On the contrary, the shoot could regenerate from putative transformed callus, selected in a medium containing 100 mg l^{-1} kanamycin. Uematsu *et al.* (1991) obtained shoots in the medium containing 25 mg l^{-1} kanamycin. Janssen and Gardner (1993) regenerated kanamycin resistant shoots from leaf discs of *A. deliciosa* cv. Hayward in presence of 100 mg l^{-1} kanamycin.

Experiments with protoplasts have demonstrated that 25 mg l^{-1} of kanamycin led to the gradual loss of the organogenic potential; however, the reduction of kanamycin concentration to 18 mg l^{-1} allowed plantlet regeneration (Oliveira *et al.*, 1994).

Different strategies have been tried to select transgenes. Janssen and Gardner (1993) added kanamycin after 2 days of co-cultivation with *Agrobacterium*, while Rugini *et al.* (1991) applied kanamycin (100 mg l^{-1}) after 2 weeks, then shoots were subcultured twice in the proliferation medium containing 50 mg l^{-1} kanamycin before transferring them to rooting medium. In order to avoid escapes, further selection was done by transferring selected shoots in the rooting medium containing kanamycin. In kiwi, the time for applying selection pressure with antibiotic is not a critical factor given its high ability

to regenerate, even in the presence of high antibiotic concentration. However, late kanamycin application, especially when the explant formed a big mass of callus is not so effective because it requires longer selection time, and the risk of somaclonal variation is very high, mainly due to an increase of ploidy level (Rugini *et al.*, 1994).

2.6 Regeneration of Whole Plant

Genetic manipulation of the plant genome by development of recombinant DNA techniques, and efficient *in vitro* culture techniques for plant regeneration from cells and tissues could lead to the development of new cultivars with desirable traits (Dandekar, 1992). Kiwifruit has demonstrated relative amenability to *in vitro* multiplication, not only by axillary bud stimulation, but also via organogenesis and, to a lesser extent via somatic embryogenesis. The recovery of transgenic plants depends on the frequency of gene introduction and the ability of the transformed cells to differentiate by efficient regeneration systems. The most common explants used for transformation experiments via *Agrobacterium* were leaf discs (Rugini *et al.*, 1989, 1991; Janssen and Gardner, 1993; Raquel and Oliveira, 1996), hypocotyls (Uematsu *et al.*, 1991; Yazawa *et al.*, 1995), protoplasts isolated from petioles (Oliveira *et al.*, 1991), and petioles of leaf explants (Yamakawa and Chen, 1996). However, according to our experience, the petioles of *A. deliciosa* give the best results in terms of regeneration and transformation efficiency.

2.6.1 Organogenesis

Actinidia species has demonstrated a remarkable organogenetic ability from different types of tissues (Revilla *et al.*, 1992). The morphogenetic responses of the explants vary with the type, combination, and concentration of growth regulators added to the basal medium. Different explant types and culture media have been used for shoot/embryo induction, regeneration, and efficient rooting for different kiwifruit genotypes (Canhoto and Cruz, 1987; Rey *et al.*, 1992; Cai *et al.*, 1993; Gonzalez *et al.*, 1995). Explants used for organogenesis are root and stem segments,

staminal filaments, immature fruits, apical meristems, and endosperms. This has allowed plants of novel genetic constitution derived from interspecific hybrids, buds, nodal segments, shoot tips, cambial tissue, callus from different organs, anthers, hypocotyls, petiole segments, leaves from axenic shoot cultures, and cell suspensions (Revilla *et al.*, 1992). Furthermore, plant regeneration from protoplasts has also been developed (Raquel and Oliveira, 1996).

2.6.2 Somatic embryogenesis

Somatic embryogenesis is a suitable technique for transformation experiments because stable transgenic plants can be obtained from a little starting material. The critical factors in kiwifruit somatic embryogenesis are genotype and explant competence, preconditioning, and culture conditions. Several attempts have been made to induce somatic embryogenesis from different tissues of *A. chinensis*, *A. arguta*, and *A. deliciosa*. In most cases, only globular stages and embryoids have been obtained and regeneration of somatic seedlings is still restricted to a few genotypes and explants (Oliveira, 1998). *A. chinensis* var. *chinensis* is highly responsive to embryogenesis. So far, explants tested for somatic embryogenesis showed different behaviors. Root, stem (Harada, 1975), and stamen filaments (Brossard-Chriqui and Tripathi, 1984) gave rise only to embryoids; endosperm tissues allowed to regenerate, some plants from embryoids (Gui *et al.*, 1982; Huang *et al.*, 1983), while Mu *et al.* (1990a) did not obtain complete plants with the same tissue of several interspecific crosses of *Actinidia*. Anthers of *A. chinensis* differentiated embryoids, which developed into bipolar heart-shaped structures (Fraser and Harvey, 1986). Precondition treatments to leaves of *A. deliciosa* cv. Hayward were successful in obtaining different developmental stages of somatic embryos (Oliveira and Pais, 1992).

2.7 Testing for Activity and Stability of Inheritance of Genes; and Adverse Effects on Growth, Yield, and Quality

Agronomic performance and inheritance of the 6-year-old transgenic plants with *rolABC* and *rolB*

and *osmotin* genes of the staminate GTH and the pistillate Hayward have been studied (Rugini *et al.*, 1996b, 1997, 1999; D'Angeli *et al.*, 2001). The most important phenotypic modifications are reported in Table 1. Field evaluations of transgenic *rolABC* plants after 15 years of the creation showed that they maintained a hairy root phenotype showing an increased lateral shoot number, smaller leaves with a narrow angle of insertion with probably modified light interception capacity (Figure 1). The transgenics propagated by cuttings maintained the same "hairy root" characteristics, and plants looked greener and better thriving than controls. However, the number of flowers per plant was lesser than the control plants because more than 60% of the flowers were single. This phenomenon is not constant during the years, depending probably to the environmental conditions before the blossom. This reduction of flower number is a negative feature for staminate plants, and for pistillate plants fruit size was smaller and fruit shape changed to rounder than control plants (Figure 2). When transgenic *rolABC* "GTH" was used as rootstock, the scion showed more branches than those grafted on untransformed rootstocks. In addition, these plants showed potentially useful characteristics with reduced leaf size, expanded root system,

and more drought tolerance (Figure 3). The pistillate cv. Hayward pollinated with transgenic staminate GTH produced regular fruits, and 50% of their seeds produced transgenic plants with characteristic "hairy root" phenotype. Normally, transgenic and nontransgenic offspring produced smaller fruit than the mother plant Hayward, except in one case among over 100 plants observed. Furthermore, the transgenics for *rolABC* showed a different internodes length, number of flowers per plant, and differences in transpiration rate (Rugini *et al.*, 1997, 1999).

The plants transformed with *rolB* were morphologically similar to untransformed controls, but their explants were more sensitive to auxin both for *in vitro* explants and *in vivo* cuttings. In fact, the *in vitro* leaf discs produced roots in the presence of very low auxin concentration and could regenerate shoots with very high 6-benzylaminopurine concentration, prohibiting regeneration of untransformed explants. *In vivo rolB* cuttings showed only abnormal basal callus formation with an auxin concentration allowing satisfactory rooting response in control cuttings. Fruit shape and size were similar to control fruits (Figure 2).

Transgenic kiwi plants of Hayward for the *osmotin* gene were obtained by Rugini *et al.* (1999) and the presence of the *osmotin* gene was

Table 1 Comparison between 8-year-old *rolABC* pistillate "GTH" plants and control plants in the experimental field

Characters	Control GTH	<i>rolABC</i> GTH
One year stem length (cm)	146.00a ^(a)	102.00b
One year shoot internode length (cm)	6.60a	3.40b
Trunk circumference (cm)	20.00a	15.00b
Leaf area (cm ²)	74.00a	35.00b
Leaf area × meter of shoot (m ²)	0.12a	0.10b
Petiole length (cm)	4.40a	1.90b
Petiole diameter (mm)	2.05	2.54b
Number of flowers/1 year vine	147.00a	59.00b ^(b)
Single flowers (%)	10.00a	62.00b ^(b)
Rooting leafy cuttings in October (%)	30.00a	75.00b
Number of roots × cutting in October	2.00a	10.00b
Assimilation [mol m ⁻² s ⁻¹ (CO ₂)]	3.15	(1.30–5.00) ^(a)
Transpiration [mmol m ⁻² s ⁻¹ (H ₂ O)]	3.70	(1.65–3.72) ^(a)
Inheritance of <i>rolABC</i> genes (%)	53	
Drought resistance (both self-rooted and grafted)	Higher	
Susceptibility to winter frost	Higher	
Susceptibility to water stress	Lower	
Susceptibility to bacteria	Slightly higher	

^(a) According to the transgenes

^(b) The average changes considerably according to the year

Figure 1 Compact vegetative habits of *rolABC* plant (a) and control kiwi plant (b) grown in the experimental transgenic field at the University of Tuscia, Italy

confirmed by D'Angeli *et al.* (2001). Fruit size and shape were similar to fruit from transgenic plants for *rolABC*, that is, smaller and rounder than controls (Figure 2). Resistance tests to *B. cinerea* in the fruits showed different response varying from moderate to high resistance depending of the clone (Figure 4). Moreover, a test for *Botritis* resistance was carried out in potted plants under greenhouse conditions. The susceptibility was determined by measuring the area of necrosis induced by mycelium or spores applied by discs of potato agar dextrose on the leaf lamina. A group of

plants showed to be more tolerant to the pathogen than both regenerated plants and the mother plant (Rugini *et al.*, 1999).

After artificial infection with *Pseudomonas syringae* and *P. viridiflava*, T₁ plants (susceptible Hayward × tolerant GTH) were found to be more sensitive to these bacteria as compared to the untransformed plants (Rugini *et al.*, 1999). A positive correlation between bacterium susceptibility and high nitrogen content was observed, which characterize the transgenic plants (Balestra *et al.*, 2001).

Figure 2 Fruit shape and size of cultivar Hayward and transgenic Hayward for *rolABC*, *rolB*, and *osmotin* genes

Overexpression of genes for modifying both resistance or susceptibility to pathogens and the sensitivity to hormones of the plant is under study (Fladung and Gieffers, 1993; Storti *et al.*, 1994).

Fung *et al.* (1998) studied the inheritance and expression of *nptII* and *gus* genes within progenies of *A. deliciosa* transgenic plants. The detailed

examination of two plants suggested that there were multiple copies of both the *nptII* and the *uidA* genes. None of the actively expressing copies of *nptII* or *uidA* were linked. Expression of GUS was variable in some progeny plants, consistent with the idea that gene silencing phenomena were operating.

Figure 4 Response of kiwifruit from transgenic plant for the *osmotin* gene, and control fruit after inoculation with *Botritis cinerea*

3. FUTURE ROAD MAP

Albeit all the benefits of the consumption of kiwifruit, the world market is small as compared with other fresh fruits. The commercial kiwi cultivars have some deficiencies that limit the marketing because there are still very few types of kiwifruit available for consumption. The potential for development of improved agronomic traits in kiwifruit employing tradition breeding and biotechnology is high. The extensive genetic variation within the genus *Actinidia* provides the opportunity for developing new and different cultivars. For example, in *A. eriantha* the vines are relatively small and nonvigorous, flowers form all over the vine including on lower axillary branches and produce the third largest fruit of the species in the *Actinidia* genus (Liang, 1980) with very high vitamin C content, and some genotypes have peelable skins. Furthermore, it flowers prolifically under greenhouse conditions and has a low requirement for winter chilling than *A. deliciosa* and *A. chinensis* (Seal, 2003; Wang *et al.*, 2006). Breeders need access to a diverse germplasm collection and must have the knowledge of the genetic variation present in them. In traditional breeding, the long generation time is the major constraint as well as the choice of the parents, especially the males, and also the different ploidy level can restrict crossing options.

The main desirable characteristics in *Actinidia* include the production of hermaphrodite plants, improvement in fruit quality, production of parthenocarpic fruits, improvement in abiotic and biotic stress tolerance, alteration of vegetative

habit, and regulation of fruit ripening. Genetic transformation programs are focused on solving the main problems by transferring one or more foreign genes, or by limiting the expression of the endogenous ones. Currently, several genes are available with known origins; others are under characterization and isolation with their own promoters from several woody plants, including kiwi (Owens, 1995).

3.1 Hermaphroditism and Parthenocarpy

Dioecism is the major limiting factor for kiwi productivity. More work is needed on the physiological and biochemical aspects of hermaphroditism. Also, the identification and isolation of genes involved in sex determination may be useful to transform genotypes of high agronomic and commercial value. The introduction of the parthenocarpic trait may help to solve problems related to fructification due to the negative dioecism character. Unfortunately, *Actinidia* species do not show any natural parthenocarpy characteristic as in aubergine (Rotino *et al.*, 1997).

3.2 Regulation on Fruit Ripening and Quality

Fruit ripening is a complex process, which involves both an increase in respiration and ethylene production, which are influenced by the orchard condition, the fruit position in the plant, and

harvest and postharvest handling (Cooper *et al.*, 2005). Due to the rapid fruit softening at maturity, regulation of fruit ripening by manipulating the genes responsible of this process could make harvesting, shipping, storage, and marketing easier. Major efforts of molecular investigations are focused on the study of genes involved in fruit development and ripening under different strategies, and transgenic plants for the antisense genes should be generated.

The polygalacturonase gene encodes poly (1,4- α -D-galacturonide) glycan hydrolase. It is one of the enzymes involved in the process by breaking down pectin, a major component of the middle lamella (Soda *et al.*, 1986; Wegrzyn and MacRae, 1992; Bonghi *et al.*, 1997). Slacking the activity of the polygalacturonase enzyme would be an important strategy for improving fruit storage and marketing. The nucleotide sequence of the polygalacturonase (PG) gene in Hayward has been determined and compared with tomato protein by Atkinson and Gardner (1993) and the antisense construct may soon be available for kiwi transformation. Later, Wang *et al.* (2000) characterized the expression of three polygalacturonase cDNA clones (CkPG A, B, and C) isolated from fruit of *A. chinensis* and they found that CkPGC gene expression was present in softening fruit, 50-fold higher than A and B as fruit passed through the climacteric, but it was also present during fruit development and harvesting prior to the onset of softening.

Demethylation of the carboxyl group of the polygalacturonic acid by the pectin methylesterase enzyme (PME) causes changes in tissue firmness during fruit maturation (Bordenave, 1996; Micheli, 2001). The pectin methylesterase inhibitor (PMEI), its amino acid sequence, basic structure, and its regulation on cell wall degradation and fruit ripening processes by interaction with PME have been reported in kiwifruit (Balestrieri *et al.*, 1990; Giovane *et al.*, 1995; Camardella *et al.*, 2000; Jiang *et al.*, 2002). Fruit ripening controlled by the production of genetically modified kiwi containing *PMEI* genes is an attractive possibility for inactivating endogenous PME activity. The expression of *PMEI* from the cultivar Hayward was studied in transgenic asparagus for two *PMEI* cDNA clones and it was found *in vivo* inhibition effects on PME activity, but the biochemical effect on cell wall metabolism and their physiological role

during plant development are not clear (Irifune *et al.*, 2004).

MacDiarmid and Gardner (1993) tried to understand why Hayward has storage properties superior to other *Actinidia* spp. They sequenced a cDNA clone with high homology to ACC-oxidase tomato gene and related genes from apple. Ikoma *et al.* (1995) cloned two ACC-synthase genes and found that KWACC2 was actively transcribed only in wounded tissue, while KWACC1 was expressed in both ethylene-treated fruit and wounded tissue. Ren *et al.* (1997a) cloned and sequenced ACC-oxidase gene from cv. Qinnei (*A. deliciosa*) and found that their DNA and amino acid sequences are 95.01% and 95.61% homologous, respectively, to those of Hayward. They also cloned and sequenced a Ca-regulated protein gene from Qinnei fruit and found that the DNA sequence is 86.16% homologous to barley (Ren *et al.*, 1997b). In addition, Xu *et al.* (1998) found that ACC synthase and not ACC oxidase is the key enzyme that controls the rate of endogenous ethylene production in fruits of *A. chinensis* (cvs. Kuimi and Hongxin).

Studies on gene expression during fruit development were carried out by Ledger and Gardner (1994), which obtained five cDNAs differentially expressed during fruit development in Hayward. Only one of them had low levels of expression in young fruit and it is induced late in fruit development and during fruit ripening, while the others are highly expressed only in young fruits but had reduced expression in late development.

Other genes involved in fruit ripening in *A. deliciosa* var. *deliciosa* and *A. chinensis* var. *chinensis* have also been identified including a cDNA clone encoding sucrose-phosphate synthase from ripening kiwifruit (Langenkamper *et al.*, 1998). Six cDNA clones (AdXET1-6) with homology to the xyloglucan endotransglycosylase (*XET*) gene were isolated from ripe kiwifruit mRNA of cv. Hayward and appeared to belong to a closely related family of genes (Schroder *et al.*, 1998), while studies on the expression pattern of *XET* gene in *A. chinensis* suggested that *XET* might be a kind of inductase leading to xyloglucan depolymeration in the fruit cell wall and does not play a key role in softening of kiwifruit after ripening (Chen *et al.*, 1999).

Actinidin, a cysteine protease expressed during fruit development and harvest time (up to 60% of the soluble proteins), is the principal

responsible of allergic reactions. Its contents in the fruit vary among species and cultivars. Possible solutions have emerged from the isolation and characterization of cDNAs encoding actinidin from kiwifruit (Praekelt *et al.*, 1988; Podivinsky *et al.*, 1989; Snowden and Gardner, 1990). Its promoter sequence (Keeling *et al.*, 1990) and its expression in transgenic petunia resembled the pattern of actinidin induction in fruit tissues of kiwifruit (Lin *et al.*, 1993). The precise location and the determination of the function of the actinidin propeptide sequences have been studied through transgenic tobacco plants for preproactinidin lacking the C-terminal propeptide, demonstrating that the actinidin CTPP is required for actinidin processing (Paul *et al.*, 1995).

Finally, fruit size and enhancement of sugar accumulation could be improved by overexpressing gene-regulating ADP-glucose-pirophosphorilase, as observed in potato tubers after introduction of this gene (Stark *et al.*, 1992).

3.3 Abiotic Stress Tolerance

Cold resistant plants are recommended due to the wide diffusion of this species in areas where the risk of early spring frost and winter frost are frequent. The *A. arguta* and *A. kolomikta* have demonstrated frost resistance and could be used to identify genes and introduce into the current germplasm. Transgenic plants with gene encoding antifreezing protein have been generated (Hightower *et al.*, 1991) and the overexpression of *Superoxide dismutase* gene has also been demonstrated to repair frost-damaged cells (McKersie *et al.*, 1993; Van Camp *et al.*, 1994). Overexpression of Arabidopsis *CBF1* gene enhances freezing tolerance by inducing genes associated with cold acclimatization could also be useful (Jaglo-Ottosen *et al.*, 1993).

Salt tolerance has been induced in tobacco plants by introduction of genes for glycerol-3-phosphate acyltransferase (Tarczynski *et al.*, 1993). Furthermore, gene identification and isolation for calcareous and drought tolerance from somaclones regenerated under selective pressure media could facilitate to obtain new cultivars by further genetic transformation (Marino and Battistini, 1990; Muleo *et al.*, 1996).

3.4 Alteration of Vegetative and Reproductive Habit

Genetic improvement in canopy architecture to produce dwarf, semi-dwarf plants with shorter shoots, unifloral buds is required for high-density orchards. Moreover, developing plants with a more expanded root system and/or with reduced water consumption could be of advantage during drought seasons or in areas with scarce water availability and/or sandy soils. Some genes of the TL-DNA of *A. rhizogenes* affecting plant growth and development have already been introduced in kiwi and in other woody fruit plants, such as cherry (Gutiérrez-Pesce *et al.*, 1998; Rugini and Gutiérrez-Pesce, 1999) and in peach (Hammerschlag and Smigocki, 1998). In all these species, reduction of plant size and apical dominance is confirmed and currently, field trials will test their agronomic value.

Another possibility offered by biotechnology for modifying growth and reproductive behavior, is the modification of plant receptors to change light perception. Phytochrome genes (*phyA*, and/or *phyB*, sense or antisense) together with other photoreceptors, control plant development, circadian rhythms, apical dominance, blossoms, growth and fruit ripening, photosynthesis products distribution, development of photosynthetic systems, transpiration control, and hormone synthesis (Tucker, 1976; Vince-Prue and Canham, 1983; Baraldi *et al.*, 1992; Muleo and Thomas, 1993, 1997). Transformation with these genes may help to generate plants with high agronomic value. *In vitro*-grown shoots of the cherry rootstock "Colt" overexpressing *phyA* of rice have demonstrated a reduction of apical dominance with red and far-red light treatments (Muleo and Iacona, 1998). This indicates that the excess of red and far-red light, generated in orchard with high-density plantation, could modify the distribution of the photosynthetic assimilate among the vegetative growing organs.

3.5 Disease and Pest Resistance

The promise of using molecular biology is that it may generate broad resistance mechanisms that have been difficult to manipulate with classical plant breeding approaches. Although currently,

pests and diseases are not the only limiting factor in kiwifruit, due to cultivation of a single variety over a wide range of geographical areas, this may cause concern in the future regarding potential pathogens causing devastating damage. For enhancing protection against fungi, besides *osmotin* gene, as already introduced in the cv. Hayward, several other genes may be introduced after having tested the product of the genes against the main fungi of kiwi such as stilbene synthase gene (Hain *et al.*, 1993), ribosome-inactivation protein gene (Logemann *et al.*, 1992), glucose oxidase gene (Wu *et al.*, 1995), and genes encoding hydrolytic enzymes such as chitinase and glucanase, which degrade fungal cell wall components (Broglie *et al.*, 1991; Yoshikawa *et al.*, 1993).

Special attention is given to polygalacturonase-inhibiting proteins (PGIPs), which specifically inhibit the activity of endo-polygalacturonases released by fungi on invasion of the plant cell wall. The complete nucleotide sequence of a potential kiwifruit cv. Hayward *PGIP* has been determined (GeneBank249063). The expression and activity of kiwifruit PGIP is expected to exhibit similar expression patterns to that shown by other *PGIP* genes of other species.

Kiwi genotypes with less susceptibility to *P. syringae* and *P. viridiflava* have been preliminarily identified in the cv. GTH, so it should be interesting to investigate both the staminate GTH and its offspring both of which showed more tolerance (Balestra *et al.*, 2001). Although it is not easy to introduce bacterial resistance in plants because the product of gene should act in the intercellular spaces; several species with enhanced resistance to bacteria have been obtained by introducing genes encoding bactericidal polypeptide as cecropine (Huang *et al.*, 1997) and its synthetic analog MB39 (Mills *et al.*, 1994), thionin (Carmona *et al.*, 1993), and attacin E (Norelli *et al.*, 1994). Particular attention should be given to human lysozyme, which confers resistance to both fungi and bacterium *P. syringae* in tobacco plants (Nakajima *et al.*, 1997).

There are two promising approaches against insect attack. The *Bt* gene from *Bacillus thuringiensis* (Vaeck *et al.*, 1987) has been successfully introduced in other species with encouraging results regarding field resistance. A cytokinin gene under the control of a wound-inducible promoter (Smigocki *et al.*, 1993) could be an alternative

to prevent leaf roller caterpillars attacking the *Actinidia* spp.

1. INTRODUCTION

1.1 History, Origin, Taxonomy, and Distribution

The genus *Passiflora* is one of the 12 genera in the family Passifloraceae of the order Violaceae, class Magnoliopsida. The center of origin is most likely tropical South America, with northern Brazil as the center of diversity (Leitão Filho and Aranha, 1974). More than 580 species are recognized, with approximately 150 originating from Brazil (Hoehne, 1946; Salomão and Andrade, 1987). The name *Passiflora*, derived from “Passion”, was given by Catholic missionaries in South America. The corona threads of the passionflower were seen as a symbol of the crown of thorns, the five stamens for wounds, the five petals and five sepals as the 10 apostles (excluding Judas and Peter), and the three stigmas for the nails on the cross. The Portuguese name, “maracujá”, is derived from the indigenous Tupi language, meaning “food shaped as a bowl”, due to the large size and shape of the fruit. The Spanish name, “granadilla”, meaning “small pomegranate”, is derived from similarity between passionfruit and pomegranate (called “granada” in Spanish due to the high number of seeds, “granas”, in the fruit).

About 50–60 species produce edible fruits that can be used for human consumption (Coppens D’Eeckenbrugge *et al.*, 2001). However, very few species are grown in a commercial scale for fruit

production. Some species are used as ornamentals or as the source of pharmaceuticals. The main cultivated species include *P. edulis* Sims f. *edulis*, *P. edulis* Sims f. *flavicarpa* Deg, *P. ligularis* Juss, *P. mollissima* (HBK) Bailey, *P. quadrangularis* L., and *P. alata* Dryand (Martin and Nakasone, 1970; Oliveira, 1987).

In most countries where passionfruit is grown, *P. edulis* f. *flavicarpa* (yellow passionfruit) is the most widely planted species. It is believed that the yellow passionfruit is the result of a cross between *P. edulis* f. *edulis* (purple passionfruit) and a closely related species, or of a mutation in *P. edulis* f. *edulis* (Oliveira and Ferreira, 1991). *P. edulis* was described in 1818 by Sims and in 1872 by Masters, and forma *flavicarpa* was proposed in 1933 by Degener (*P. edulis* f. *flavicarpa*). Therefore, forma *edulis* (*P. edulis* f. *edulis*) was necessarily established, in accordance with the International Code of Botanical Nomenclature. Both forms are subspecific categories, often cited erroneously (e.g., *P. edulis* var. *flavicarpa*) or incompletely (e.g., *P. edulis*) (Bruckner *et al.*, 2002). *P. edulis* f. *edulis* and *P. edulis* f. *flavicarpa* have differences in fruit size and external color, flavor, and resistance to a number of diseases (Martin and Nakasone, 1970). The external color of the fruit, purple or yellow, is apparently controlled by one pair of co-dominant alleles, and the F₁ progeny of a cross between the two forms produces fruits with an intermediate, reddish purple color (Nakasone *et al.*, 1967). The species *Passiflora edulis* f. *flavicarpa* will be referred

to simply as yellow passionfruit throughout this text.

1.2 Botanical Description

All species in the genus are characterized by possessing flowers with five stamens, five petals, and five sepals, with an upright ginandrophore with free stamens and three stigma (Salomão and Andrade, 1987). Flowers are usually large (5–7 cm in diameter), white, pink, red, or purple, with a pink, red, or white corona of filaments (Figures 1a and b). Most species grow as perennial or semiperennial vines, with alternate, oblong or oval leaves (Figures 1c and d).

Passionfruit is essentially cross-pollinated. The most efficient pollinating agents are carpenter bees (*Xylocopa* spp.), which are large enough to

reach the stigma after removing pollen grains. European honeybees (*Apis mellifera*) visit the flowers and actually remove pollen, but are not large enough to reach the stigma and pollinate the flower. Therefore, the presence of honeybees can actually decrease fruit yield in commercial plantations. Pollination by wind is negligible due to the large size and sticky nature of the pollen grain (Bruckner *et al.*, 2000). Besides floral structure, cross-pollination is favored by self-incompatibility, which was reported for *P. edulis* as far back as 1868 (Munro cited by Nettancourt, 1977). Self-incompatibility in yellow passionfruit is sporophytic, occurring in the stigma and resulting in inhibition of growth of the pollen tube. Early studies indicated that self-incompatibility was governed by a single gene with multiple alleles (Bruckner *et al.*, 1995). However, analysis

^(a)Modified from Cuco *et al.* (2005)

of homozygous families for the different alleles identified new phenotypes in these families, a clear evidence that another gene would be acting (Rêgo *et al.*, 1999). Indeed, the presence of a second gametophytic gene was suggested by the analysis of families originated from crosses among plants that presented differences in reciprocal crosses (Suassuna *et al.*, 2003). Compatibility would require that the maternal plant be homozygous for the gametophytic *G* locus and receive pollen grain from a heterozygous plant. Moreover, both plants must have the same genotype at the sporophytic, *S* locus. The reciprocal cross is incompatible (Suassuna *et al.*, 2003). The plant can also be vegetatively propagated by cuttings or grafting.

Passionflowers are tropical plants and therefore are best adapted to grow at warmer temperatures with high rainfall. Yellow passionfruit is cultivated mostly in tropical lowlands, while purple passionfruit is located mostly in moderately higher altitudes (1000–2000 m). The plant is intolerant to frost.

Despite its economical importance and the interest of botanists, information on passionfruit cytogenetics remains scarce. Only a fraction of the known species of *Passiflora* have been studied in terms of genome composition (Snow, 1993). Most species have $2n = 12$ or 18. However, species with $2n = 14$, 20, 24, 27, 36, or 84 are also known, such as *P. suberosa*, *P. foetida*, and *P. pulchella* (Martin and Nakasone, 1970; Lopes, 1994). The horticulturally important species, such as *P. edulis*, have $2n = 18$.

The karyotypes of yellow passionfruit, *P. amethystina* and *P. cincinnata*, previously used to obtain somatic hybrids by protoplast fusion

(Vieira and Dornelas, 1996), were recently described in detail. Their karyotypes were symmetric, i.e., the species have preferentially metacentric chromosomes with subtle differences in the morphology of some chromosomes among species (Table 1). These data were integrated with the physical mapping of the 45S ribosomal DNA (rDNA) (18S–5.8S–26S rRNA genes) and 5S rDNA loci using fluorescent *in situ* hybridization (FISH), and with the pattern of fluorescent staining with chromomycin A3. FISH signals of 45S rDNA were localized on the secondary constriction and satellite of two chromosome pairs, identified as 8 and 9, in all three species. An additional site was observed on the long arm of chromosome 1 in *P. amethystina* (Cuco *et al.*, 2005).

A number of potentially useful species have been characterized in terms of chromosome number as well as agronomical traits. *P. setaceae* was shown to have $2n = 18$ chromosomes and displaying resistance to sudden death and *Fusarium* wilt (common diseases in commercial fields of yellow passionfruit) (Soares-Scott, 1998). *P. quadrangularis*, *P. serrato-digitata*, and an interspecific hybrid between *P. edulis* \times *P. incarnata* have $2n = 36$ chromosomes (Soares-Scott, 1998). The karyotype of *P. nitida*, an Amazonian species with the potential for commercial cultivation as well as a source of resistance genes to sudden death, was characterized. *P. nitida* has $2n = 18$ chromosomes, with secondary constrictions in pairs 3, 4, and 8. The constriction in chromosome 3 differentiates *P. nitida* from the other species within the genus *Passiflora* (Passos, 1999).

The importance of information on chromosome number is demonstrated by the observation

that interspecific compatibility is high among species with $2n = 18$ chromosomes (Martin and Nakasone, 1970; Soares-Scott, 1998). Interspecific hybrids, either natural or artificial, have been obtained and shown to have high-agronomic potential, especially in terms of disease resistance. However, information on several sections and subgenera remains unavailable.

Genome size variation in some *Passiflora* species has been estimated (Souza *et al.*, 2004). 2C DNA content and genome sizes ranged from 1.83 to 5.36 pg (picogram) and 896–5252 Mbp (mega base pairs), respectively, among the species analyzed, as follows: yellow passionfruit, 3.21 pg and 3146 Mbp; *P. quadrangularis*, 5.36 pg and 5252 Mbp; *P. laurifolia*, 3.88 pg and 3802 Mbp; *P. giberti*, 3.92 pg and 3842 Mbp; *P. edmundoi*, 3.40 pg and 3362 Mbp; *P. mucronata*, 3.43 pg and 3332 Mbp; *P. edulis* f. *edulis*, 3.16 pg and 3096 Mbp; and *P. suberosa*, 1.83 pg and 896 Mbp.

1.3 Economic Importance

Brazil is the world's largest producer and consumer of passionfruit since the mid 1970s. Total production in 2004 reached over 490 000 metric tons in approximately 36 000 hectares, representing 60% of the world's production (IBGE, 2004). Over 95% of the production is comprised of yellow passionfruit, and about 35% of this is destined for processing in the form of concentrated juice. Australia, Colombia, Ecuador, Peru, and South Africa also grow significant acreages of passionfruit, but this acreage is more evenly divided among yellow passionfruit, purple passionfruit, and *P. alata* (sweet passionfruit), and the fruit is mostly destined for fresh market consumption.

For yellow passionfruit, yields can be as high as 75 tons of commercial fruit per hectare with the adoption of a few agronomical practices: use of certified seeds, irrigation, and manual pollination (Meletti and Maia, 1999). Commercial plantations have the potential to remain productive for up to 5 years. However, the incidence of diseases (specially passionfruit woodiness and *Fusarium* wilt) usually restricts commercial production to 1 or 2 years in most regions of Brazil and also in Australia and South Africa.

Besides fruit production for human consumption, several species of passionflower are grown as

ornamentals, due to their spectacular flowers and vigorous evergreen foliage. In addition, medicinal use is quite widespread in Brazil, due to the properties of passiflorine, a natural sedative present at high concentrations in the leaves and fruit of several species (Ruggiero and Nogueira Filho, 1994).

1.4 Traditional Breeding

Passionfruit is a crop of relatively recent commercial cultivation, displaying a high degree of genetic variability for most traits related to plant development and fruit production (Bruckner *et al.*, 2002). For example, a population derived from a single cross between two Brazilian accessions, "IAPAR-06" and "IAPAR-123", was evaluated in two harvest seasons in a triple 10×10 square lattice design and displayed a wide genetic variance for several traits related to yield and fruit quality. The estimate for broad-sense heritability ranged between 53% and 83% (Moraes *et al.*, 2005).

This variability can be easily exploited by mass selection and selected populations can be found regionally in Brazil and other countries. Germplasm characterization started in the late 1970s and is still a major objective of several breeding programs (Bruckner *et al.*, 2002). Most breeding programs employ one (or an association) of three strategies—mass selection, selection with progeny tests, and interspecific hybridization.

The objective of breeding programs emphasizes traits related to fruit production, including those which favor industrial processing: fruit size/weight, firmness, pulp content, shape, color, flavor, and aroma (Vieira and Carneiro, 2004). Acidity and total soluble solids are also important for juice processing.

Most breeding programs are targeted to purple or yellow passionfruit, and the development of cultivars has three main objectives: (i) yield, including a short juvenile period and self-compatibility, (ii) fruit quality, including uniform ripening, and (iii) disease resistance (Bruckner *et al.*, 2002; Vieira and Carneiro, 2004). Of these three, disease resistance has been the least successful and is the one for which biotechnology holds the greatest promises.

Fruit size/weight is an important trait, directly related to yield. Different studies have indicated

large variations for this trait in *Passiflora* germplasm. Most currently available cultivars produce fruits that range from 50 to 130 g. Fruit size/weight is also highly dependent on cultural practices. Manual pollination alone can increase average fruit weight from 62 to 112 g (Ruggiero *et al.*, 1976). Some recently developed interspecific hybrids can reach an average fruit weight of 220 g (Bruckner *et al.*, 2002).

The breeding program at the Instituto Agrônomo de Campinas (IAC, Campinas, São Paulo state) has been the most active and successful in Brazil. Using mass selection with progeny tests in preselected populations of yellow passionfruit, gains of up to 100% in yield, fruit size and weight, and number of seeds per fruit were obtained with four rounds of selection. Gains in total soluble solids and percentage of pulp were significant, although not that high. Some selections had an average fruit weight of 150 g, compared to 90 g for the original genotypes, and average fruit diameter of 9 cm compared to 6 cm (Melleti *et al.*, 1992). Selected populations were then subjected to interspecific hybridization. The descendants producing better fruits were backcrossed with high-yielding ($>30 \text{ t ha}^{-1}$) parents. This work generated eight commercially promising combinations producing large, oval fruit with high soluble solids content. Two additional backcrosses generated additional gains in fruit qualitative traits and yield and resulted in the first three yellow passionfruit cultivars ever released in Brazil, “IAC-273, -275, and -277” (Melleti, 1999). These cultivars produce fruits with an average weight of 170–220 g, 9 cm of longitudinal diameter and 7.3 cm of transversal diameter, 50% pulp, $>15^\circ\text{Brix}$ of total soluble solids, and over 370 seeds per fruit, and reach an average yield of $45\text{--}50 \text{ t ha}^{-1}$ with manual pollination but no irrigation (Melleti, 1999).

The generation of interspecific hybrids is a potential tool for the production of high-yielding, disease-resistant passionfruit cultivars. Traditionally, emphasis has been placed upon the transfer of favorable traits from wild species to *P. edulis*. However, most interspecific hybrids present developmental problems, including male sterility, low viability of pollen, and limited flowering. A *P. nitida* \times *P. edulis* hybrid resulted in a single abnormal descendent, which did not produce a single flower in four years (Soares-

Scott, 1998). A *P. edulis* \times *P. incarnata* hybrid produced viable progeny, although pollen grains had significant variations in size. These variations were shown to be correlated with variations in chromosome number in the pollen grains (Soares-Scott, 1998). A *P. edulis* \times *P. incarnata* hybrid with tolerance to cold and to severe strains of passionfruit woodiness virus (PWV) was obtained in Australia (Nakasone and Paull, 1998) and has been maintained by grafting onto yellow passionfruit root stocks.

Soil-borne diseases and viral diseases are limiting factors for passionfruit production in all areas of the world with significant acreages. The wilt disease caused by *Fusarium* is the most important soil-borne disease of passionfruit, due to its rapid progress that inevitably culminates with plant death and the capacity of the fungus to survive in the soil in the absence of the host for at least 10 years (Oliveira and Ferreira, 1991). In South Africa, the disease is controlled by using *P. caerulea* as root stock (Nakasone and Paull, 1998). Grafting is not a cultural practice in Brazil, but due to the failure of incorporating resistance to *Fusarium* wilt into commercial yellow passionfruit germplasm, the use of tolerant or resistant root stocks, such as *P. alata*, *P. caerulea*, or *P. macrocarpa*, has been investigated and encouraged as a way to control the disease (Bruckner *et al.*, 2002).

Passionfruit woodiness disease (PWD) is the most important viral disease of yellow passionfruit worldwide. The disease is characterized by mosaic and distortion of the leaves and by “woodiness” of the fruit, which become dwarfed and lose much of the pericarp, therefore becoming unmarketable. Until recently, it was attributed to a single potyvirus species, PWV. However, the molecular characterization of viral isolates causing the disease in the African continent and in Brazil identified a second species, cowpea aphid-borne mosaic virus (CABMV), as an etiological agent of the disease (McKern *et al.*, 1994; Sithole-Niang *et al.*, 1996; Nascimento *et al.*, 2006). In fact, CABMV is the predominant, if not the single, etiological agent of PWD in Africa and Brazil. The control of PWD is quite unsatisfactory, due to the noncirculative nature of both PWV and CABMV in their aphid vectors, and the existence of several wild hosts of both viruses, including several leguminous plants (family Fabaceae).

In Australia, the use of tolerant *P. edulis* f. *edulis* and yellow passionfruit hybrids is a common practice to control the disease (Pares and Martin, 1984; Fitzel *et al.*, 1985). However, these hybrids produce fruits with a pinkish color, which is not accepted in some markets. In South Africa, a breeding program was started in 1995 to obtain PWD-resistant cultivars (Breedt, 1997). A total of 27 interspecific hybrids among yellow passionfruit, *P. edulis* f. *edulis*, and *P. quadrangularis* were obtained, which eventually generated three genotypes with tolerance to *Fusarium* wilt. However, resistance to PWD was not obtained. In Brazil, CABMV-tolerant or resistant cultivars are not available, and the prospects for their availability are slim, due to the natural barriers for transfer of sources of resistance from wild *Passiflora* species to yellow passionfruit (Bruckner *et al.*, 2002).

1.5 Molecular Breeding: Linkage Maps and QTL Mapping

The locations on chromosomes of each (or a cluster) of the genes controlling a quantitative trait are called quantitative trait loci (QTL). Nowadays, in addition to the traditional methods for selecting complex characteristics, plant breeders combine phenotypic testing and molecular mapping to dissect the inheritance of quantitative traits. This is a consequence of a huge effort for developing molecular markers in the last 20 years. DNA markers are stable changes in short nucleotide sequences that occur at specific loci. Usually, they follow the same Mendelian rules of inheritance. For this reason, molecular markers have been extensively used for constructing saturated linkage maps and to study genetic diversity.

Linkage maps represent the location and the order of genes and DNA sequences, for example, molecular markers on a chromosome. Depending on the linkage forces, one might expect that molecular marker variants are inherited along with the allele the breeders are interested. Therefore, molecular maps can be used to map loci that control a quantitative trait. A new avenue, called marker-assisted selection has been open in recent years, and it has been proven to be effective especially for traits of low heritability and less costly to evaluate (reviewed by Francia *et al.*, 2005).

The development of genetic maps for auto-incompatible species, such as the yellow passionfruit, is restricted due to the unfeasibility for obtaining traditional mapping populations based on inbred lines, like F_2 , BC_1 , or recombinant inbred lines. Therefore, *Passiflora* linkage maps were constructed using an F_1 population. The two-way pseudotestcross strategy (Grattapaglia and Sederoff, 1994) and dominant markers, for example, random amplified polymorphic DNAs (RAPDs) and amplified fragment length polymorphisms (AFLPs) were employed (Carneiro *et al.*, 2002; Moraes, 2005; Lopes *et al.*, 2006). These PCR-based markers segregate in the F_1 population in a 1:1 or 3:1 fashion, being recognized as monoparental or biparental loci, respectively. Due to the lack of genetic information from these markers in one of the parents (i.e., homozygous for the null allele), two individual (parental) maps are obtained. On the other hand, if biparental markers are simultaneously analyzed, the homology of the linkage groups should be established. Using the same strategy, parental maps were constructed in other fruit species, such as kiwifruit (Testolin *et al.*, 2001) and apple (Kenis and Keulemans, 2005) as one definitive linkage map for each cultivar is desired.

Based on those linkage maps several genes were mapped in the yellow passionfruit. As mentioned, an F_1 population was evaluated during two harvest seasons, and genetic and phenotypic parameters were estimated for yield and fruit quality traits (Moraes *et al.*, 2005). The population displayed a wide genetic variability, as shown by the high significance of the genotype effects. This has permitted testing for associations between the markers (presence vs. absence) and the expression of the traits in the population. QTL analyses were performed simultaneously on each parental map. The composite interval mapping proposed by Zeng (1993, 1994) was preferred. In order to increase the power of QTL detection, both parental maps were used simultaneously as previously suggested by Hayashi and Awata (2004). A total of 40 QTLs were mapped on the parental linkage groups (Moraes, 2005). Approximately 27% of the QTLs identified had an intermediate phenotypic effect, explaining more than 12% of the phenotypic variance. Among other traits, these loci were detected for fruit yield, total number of fruits, length, and width of fruits (Figure 2).

Figure 2 QTL mapping (colored bars, on the left) in one of the yellow passionfruit linkage groups, constructed based on AFLP markers (note that correlated traits, e.g., number, weight, and length of the fruit tend to map on the same regions)

Moreover, important quantitative resistance loci (QRL), related to the response of the same F_1 population to inoculation with isolates of *Xanthomonas axonopodis* pv. *passiflorae* were mapped (Lopes *et al.*, 2006). This pathogen is frequently found in passionflower orchards, being very destructive to the crop. The mechanisms of inheritance of resistance are poorly understood and further breeding progress is difficult to obtain. As reported for other crops (Studer *et al.*, 2006), only a few major QTLs explaining 16.5% of the

total phenotypic variation for diseased leaf area were detected in yellow passionfruit. QRLs for partial resistance tend to map at genomic regions near clustered resistance genes (R) in several plant species. Based on this idea, an investigation to assess the number of analogous R genes in yellow passionfruit was initiated (Consoli *et al.*, 2006). Although many important questions remain to be answered regarding R genes, specific passionflower resistance genes will certainly be cloned in the near future.

1.6 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

As outlined in Section 1.4, conventional breeding is limited, at times quite severely, by natural barriers related to interspecific incompatibility among many species of *Passiflora*, as well as self-incompatibility in most commercially important species, including yellow passionfruit. Also, the semiperennial nature of the plant and its long juvenile period (at least 90 days) necessarily turn conventional breeding into a medium- to long-term endeavor. Therefore, passionfruit is one of the crops in which immediate benefits of transgenic breeding are easier to appreciate. For traits such as virus resistance, in which the resistance gene is derived from the pathogen's own genome and therefore is readily available, resistant plants could, in theory, be generated in a very short period of time. Even for more complex traits, transgenic approaches hold the promise of faster and better results when compared to conventional breeding.

2. TRANSGENIC PASSIONFRUIT

2.1 Tissue Culture-based Techniques Applied to Passionfruit Genetic Transformation

Tissue culture studies in *Passiflora* were initiated as early as 1966 (Nakayama, 1966) with shoot production from stem segments of mature plants of *P. caerulea*. Micropropagation of yellow passionfruit and *P. mollissima* was further reported (Moran Robles, 1978, 1979). Since then, an increasing number of reports on tissue culture-based techniques applied to the genus have been published (reviewed by Vieira and Carneiro, 2004). The development of plant genetic transformation techniques has opened up a new approach to plant breeding of several tropical fruit crops, including passionfruit (Gómez-Lim and Litz, 2004). Genetic transformation is an important strategy for obtaining disease-resistant plants of yellow passionfruit and *P. edulis* f. *edulis*, which is specially relevant since passionfruit woodiness, (caused by PWV or CABMV), *Fusarium* wilt (caused by *Fusarium oxysporum* f. sp. *passiflorae*), and bacterial blight (caused by *Xanthomonas axonopodis* pv. *passiflorae*) are the major limiting

factors for the crop (Vieira and Carneiro, 2004; Alfenas *et al.*, 2005; Trevisan *et al.*, 2006).

2.1.1 Micropropagation

An efficient *in vitro*-based plant regeneration system is a prerequisite for genetic transformation approaches, thereby providing a practical baseline for improved micropropagation systems and/or clonal plant production. Thus, the development of any novel cultural regime that facilitates clonal propagation of commercial *Passiflora* species is of utmost importance (Davey *et al.*, 2003). Although several protocols for *in vitro* propagation and regeneration of *Passiflora* spp. are available (Table 2) and can be used for *Agrobacterium*-mediated transformation, passionfruit micropropagation is far from being routine due to low multiplication rates, even though several studies have been reported. Low regeneration frequencies and inconsistent results continue to offer a challenge to study the effects of explant source on *in vitro* regeneration of *Passiflora* species.

As for other species, the achievement of reliable transformation protocols in the genus *Passiflora* depends on the establishment of an efficient regeneration procedure, high transformation frequency, and optimum selection for regenerating transformed cells. This can be obtained by the interplay of several factors including plant genotype, choice of explant source, concentration and combination of plant growth regulators, nutrient medium composition, and culture environment (light quality and quantity or absence of light; temperature; and gaseous environment) (Phillips, 2004).

De novo regeneration of passionfruit has been achieved via the organogenic pathway from explants derived from seedlings. Organogenesis occurs either from callus (Nakayama, 1966; Moran Robles, 1979; Mourad-Agha and Dexheimer, 1979; Scorza and Janick, 1980; Kantharajah and Dodd, 1990; Vestri *et al.*, 1990; Desai and Mehta, 1985; Monteiro *et al.*, 2000) or directly from the explant (Dornelas and Vieira, 1994; Kawata *et al.*, 1995; Faria and Segura, 1997a; Cancino *et al.*, 1998; Jasrai and Mudgil, 1999; Otahola, 2000). Cytokinins, especially 6-benzyladenine (BA), have been demonstrated to be the most important growth regulator in relation to regeneration

^(a) Adapted from Vieira and Carneiro (2004)

(Table 2). However, thidiazuron (TDZ) has been used alternatively to induce organogenic responses in passionfruit cultured explants (Table 2).

To better characterize the structural aspects involved in shoot organogenic cultures, anatomical studies have been carried out (Moran Robles, 1979; Scorza and Janick, 1980; Biricolt and Chiari, 1994; Appezzato-da-Glória *et al.*, 1999; Biasi *et al.*, 2000; Reis, 2001; Lombardi, 2003; Dias, 2006; Felismino, 2005). A number of highly comprehensive and descriptive anatomical studies of *in vitro* organogenesis of yellow passionfruit, involving histochemistry, light, and electron (scanning electron microscope and transmission electron microscope) microscopy, have been published (Appezzato-da-Glória *et al.*, 2005; Fernando, 2005). These anatomical characterizations and the better knowledge of the cell and tissue layers involved in the morphogenic events leading to regeneration may contribute positively to increase the efficiency of transformation, as well as laying the basis for the genetic transformation of different *Passiflora* species by means of biolistics- and *Agrobacterium*-mediated gene transfer techniques.

It is well known that light influences the morphology of tissue-cultured plants, and light requirements for morphogenesis are different for each explant type and among different stages of micropropagation. Several authors have discussed the effect of light irradiation on the morphogenic potential of *Passiflora* species (reviewed by Vieira and Carneiro, 2004). However, for yellow passionfruit, a wide range of variation in light irradiation was detected among these reports: dark conditions or $23 \mu\text{M m}^{-2} \text{s}^{-1}$ (Appezzato-da-Glória *et al.*, 1999; Monteiro *et al.*, 2000), $9.75 \mu\text{M m}^{-2} \text{s}^{-1}$ (Ribas *et al.*, 2002), $22\text{--}25 \mu\text{M m}^{-2} \text{s}^{-1}$ (Dornelas and Vieira, 1994; Barbosa *et al.*, 2001; Koch *et al.*, 2001), $36 \mu\text{M m}^{-2} \text{s}^{-1}$ (Reis *et al.*, 2003, 2005), $20\text{--}55 \mu\text{M m}^{-2} \text{s}^{-1}$ (Hall *et al.*, 2000), $56 \mu\text{M m}^{-2} \text{s}^{-1}$ (Moran Robles, 1979), $80 \mu\text{M m}^{-2} \text{s}^{-1}$ (Faria and Segura, 1997a), $90 \mu\text{M m}^{-2} \text{s}^{-1}$ (Faria and Segura, 1997b; Isutsa, 2004), $180 \mu\text{M m}^{-2} \text{s}^{-1}$ (Biricolt and Chiari, 1994), all under 16 h-photoperiod, and $30 \mu\text{M m}^{-2} \text{s}^{-1}$ under continuous light (Kuriyama *et al.*, 1998). However, up to now the only systematic study on the influence of various irradiances on passionfruit *in vitro* regeneration responses was reported by Alexandre (2002, 2006). Several irradiances (12, 25, 50, 100, $150 \mu\text{M m}^{-2} \text{s}^{-1}$) were evaluated,

and hypocotyl segments and stem apices excised from yellow passionfruit plantlets showed a better adaptation to the lowest irradiances (Alexandre, 2006). Markedly, the increase in irradiance incidence on the hypocotyl segments and stem apices affected the ethylene emission rate and CO_2 evolution. In addition to that, there was a relationship between ethylene production and biosynthesis or leaf pigment degradation, and the potential quantum production of photosystem II, whereas the latter is indicated for measuring the plantlet stress levels. In the organogenic process, a direct relationship was observed between sprout formation at the highest irradiances and an increase in peroxidase activity, as well as a decrease in catalase and superoxide dismutase activities.

Regarding the importance of the physiological status of the donor plants of the explants, the age and physiological condition of donor plants was investigated by Becerra *et al.* (2004). The effect of explant source on *in vitro* morphogenesis was studied by comparing the response of explants collected from young plants, *in vitro* plantlets, and reinvigorated adult plants. Highest *de novo* shoot production was observed in explants from 2-months-old plants cultured in Murashige and Skoog (MS) medium (Murashige and Skoog, 1962) supplemented with $4.44 \mu\text{M}$ BA and $2.32 \mu\text{M}$ kinetin. Accordingly, the organogenic response varied with the time of the year when the explants of yellow passionfruit and *P. alata* were collected, something which is apparently related to the environmental conditions in which the seedlings were maintained under greenhouse conditions (Monteiro-Hara, 2000).

The supplementation of the growth media with coconut water (5–10%) improved morphogenic responses of several passionfruit species, including *P. quadrangularis* (Mourad-Agha and Dexheimer, 1979), *P. edulis* f. *edulis* (Kantharajah and Dodd, 1990), yellow passionfruit, *P. giberti*, *P. mollissima* and *P. maliformis* (Dornelas and Vieira, 1994), *P. edulis* \times yellow passionfruit (Hall *et al.*, 2000), and *P. cincinnata* (Lombardi, 2003; Fernando, 2005; Reis, 2005). It appears that for some plant species, including passionfruit, coconut water provides growth-stimulating substances which are essential for optimal regeneration, promoting the rapid development of shoots and increasing shoot number and/or height. The *in vitro* response of yellow passionfruit was also affected by the nature

of the gelling agent added to semisolid or solid media (Reis, 2001; Reis *et al.*, 2005). The gelling agents influenced organogenesis in different ways. Agargel and Phytigel allowed better organogenic responses in relation to agar. A direct relation between agar purity and improved morphogenic responses was not observed. However, the effectiveness of the selective antibiotic kanamycin decreased in media solidified with Phytigel. In view of the results, the appropriate choice of the gelling agent should be taken into account, considering its effects upon *in vitro* morphogenesis and availability of the selective agent.

As a climacteric species (Shiomi *et al.*, 1996; Mita *et al.*, 1998) it is expected that ethylene sensitivity is maintained under *in vitro* culture systems. Therefore, several regeneration protocols have considered the use of ethylene inhibitors as beneficial for enhancing morphogenic responses (Faria and Segura, 1997a; Barbosa, 1999; Barbosa *et al.*, 2001; Reis, 2001, 2005; Reis *et al.*, 2003; Trevisan and Mendes, 2005; Trevisan *et al.*, 2006), suggesting that an improvement on the number of gaseous changes between the internal atmosphere of the culture vessels and the surrounding atmosphere may be beneficial to better manipulate the growth and differentiation of micropropagated passionfruit, as well as lessening the negative effects of ethylene.

2.1.2 Somatic embryogenesis

The first report on the induction of somatic embryogenesis in the genus was for *P. giberti* by Otoni (1995). The author reported the establishment of embryogenic cell suspensions initiated from embryogenic leaf cultures. Cell suspensions, maintained in AA2 medium (Abdullah *et al.*, 1986) were used to establish a regeneration protocol based on isolated and cultured protoplasts (Otoni, 1995; Anthony *et al.*, 1999).

Even though histological analyses suggested that TDZ induces structures that resembled early staged somatic embryos (Monteiro-Hara, 2000; Felismino, 2005), no further confirmation was provided in terms of embryo development and further conversion into plants.

The induction of embryogenic calli lines from hypocotyls, anthers, and zygotic embryo explants of *P. cincinnata* has been recently achieved

(Otoni, unpublished results). Embryogenic lines were maintained in semisolid or liquid media, established from primary or secondary embryos, remaining highly proliferative. Embryo-derived plants have been successfully recovered and acclimatized under greenhouse conditions. Further studies were reported to be directed at synchronizing hystodifferentiation of the embryogenic cultures and to produce synthetic seeds. Furthermore, this morphogenic pathway has been exploited to generate fully acclimatized transgenic plants of *P. cincinnata* expressing β -glucuronidase (*gus*) and green fluorescent protein (*gfp*) genes, by means of sonication-assisted *Agrobacterium* transformation.

2.1.3 Anther culture

P. edulis was assessed for plant regeneration potential using anthers at the tetrad or early-uninucleate microspores stage as explants. However, regeneration was not obtained from calli derived from these anthers, and neither was the callus ploidy level assessed (Tsay *et al.*, 1984). Nevertheless, establishing a protocol for the development of anther culture- or microspore-derived embryogenic haploid lines represents a promising step to generate transgenic plants without hemizygous transformants. Highly proliferative embryogenic calli lines have been established for *P. cincinnata* (Otoni, unpublished results). However, flow cytometry analysis revealed the diploid nature of all regenerated embryogenic-derived plants. Nonetheless, as previously mentioned, these embryogenic lines have been used to generate transgenic plants.

2.1.4 Protoplast-based regeneration systems

Interspecific sexual hybridization has been attempted in several *Passiflora* breeding programs, using wild germplasm to transfer disease resistance and other potentially desirable traits into cultivated species. However, fertile hybrids have been difficult to obtain. Somatic hybridization provides a means of circumventing such sexual incompatibilities and therefore could be used as an alternative method for achieving gene

flow between *Passiflora* species. Indeed, novel fertile intergeneric somatic hybrids have been obtained between cultivated species (specially yellow passionfruit) and several wild *Passiflora* species (Dornelas *et al.*, 1995; Otoni *et al.*, 1995a; Vieira and Dornelas, 1996; Vieira and Carneiro, 2004). Combinations between yellow passionfruit and *P. amethystina* were further grown to maturity and characterized under field conditions (Barbosa and Vieira, 1997; Vieira and Carneiro, 2004).

A prerequisite for the production of somatic hybrids is the development of protoplast-to-plant regeneration systems. To date, plant regeneration from *Passiflora* species has been reported by shoot regeneration via organogenesis from mesophyll cells of cultivated and wild passionfruit species (d'Utra Vaz *et al.*, 1993; Dornelas and Vieira, 1993; Dornelas, 1995; Dornelas *et al.*, 1995; Otoni, 1995; Otoni *et al.*, 1995a, b, 1996).

The relative wide range of *Passiflora* species for which protoplast-to-plant regeneration systems have been established, either from cell suspension cultures (Dornelas, 1995; Dornelas *et al.*, 1995; Otoni, 1995; Anthony *et al.*, 1999) or directly from mesophyll cells, as well as the high protoplast yield, plating, and plant regeneration efficiencies usually observed, should allow the use of *Passiflora* protoplast systems not only for somatic hybridization, but also for physiological studies at the cellular level with the exploitation of possible protoclonal variation and direct gene transfer. Indeed, the later has been attempted by Monteiro (2005). However, due to the easiness of manipulating leaf or hypocotyl explants, as compared to protoplasts, the author chose to incorporate the *attacin A* (*attA*) gene by means of *Agrobacterium tumefaciens*. In conclusion, considering the extensive and reproducible works that have been reported, the protoplast-based regeneration systems already existent for *Passiflora* can be used as a basis for the development of plant transformation protocols or for studies of transient gene expression or viral replication (including virus-induced gene silencing) on freshly isolated and electroporated protoplasts.

2.1.5 *In vitro* conservation

In view of the world tendency to eliminate wild species as a consequence of deforestation, some

Passiflora species are endangered, and genotypes that could have been useful for breeding programs have disappeared. *In vitro* conservation based on shoot cultures (Vieira and Carneiro, 2004) or zygotic embryo culture (Guzzo *et al.*, 2004) not only provides a continuous source of material, but also represents an interesting approach for germplasm collection and preservation. A germplasm collection of *Passiflora* has been established based on shoot culture maintenance of wild species and somatic hybrids, with subcultures at 45–60-day intervals (Vieira, 2000; Vieira and Carneiro, 2004). This technology has also a great application if extended to the conservation of transgenic plants under laboratory conditions, ideally extending this possibility to the ultra-low-temperature conservation via cryopreservation of meristems, internodal or nodal explants, embryogenic cell suspension lines, somatic embryos, zygotic embryos, and also seeds, using vitrification-based procedures (reviewed by Engelmann, 2004).

2.2 Transgenics Developed

A number of reports of genetic transformation of passionfruit have appeared in the literature, starting with Manders *et al.* (1994). All of these reports deal with yellow passionfruit, with the majority concentrating on the validation of genetic transfer and tissue culture regeneration protocols and having no short-term commercial application. The exceptions are the reports by Alfenas *et al.* (2005) and Trevisan *et al.* (2006), which deal with the production of transgenic yellow passionfruit plants resistant to passionfruit woodiness and eventually could lead to large scale deployment.

Manders *et al.* (1994) were the first ones to report the genetic transformation of a species of *Passiflora*. Leaf disks and stem segments of yellow passionfruit were used as explants, which were co-cultivated with *A. tumefaciens* strain LBA4404 harboring the co-integration vector pMON200. Four plants were regenerated from leaf explants after 20 days of co-cultivation on agar-solidified MS medium containing 4.43 μ M 6-benzylaminopurine (BAP) and 86 μ M kanamycin. The four plants were rooted by transfer to MS medium with 14.7 μ M indole-3-acetic acid (IAA), 2.68 μ M α -naphthalene acetic acid (NAA), and 172 μ M kanamycin for 7 days, followed

by MS medium with the same concentration of kanamycin but lacking growth regulators. Rooted plants were transferred to soil and grown to maturity. Three of the plants synthesized nopaline and expressed neomycin phosphotransferase activity. The presence of the *nptII* gene was confirmed by dot blot hybridization and polymerase chain reaction (PCR) analyses in three out of the four plants. These results were expanded by Silva (1998), who demonstrated that foliar explants of yellow passionfruit are tolerant to concentrations as high as 172 μM of kanamycin. Shoot regeneration was actually enhanced at 86 μM of kanamycin. Likewise, root elongation was not inhibited even at 172 μM of kanamycin. Therefore, different selection agents (e.g., hygromycin) should be used to avoid escapes and thus to increase transformation efficiency.

Lin (1998) reported the genetic transformation of purple passionfruit (*P. edulis* f. *edulis*) mediated by *Agrobacterium rhizogenes* strain MAFF03-01724. The bacteria were smeared over a stem segment on MS solid medium. After 4 weeks, adventitious roots derived from tumors were removed and cultured on MS medium with cefotaxime. Shoots were regenerated by transferring roots to MS medium supplemented with BAP and 2,4-dichlorophenoxyacetic acid (2,4-D).

Genetic transformation using biolistics was achieved by Takahashi (2002) and Monteiro (2005), with the objective of obtaining transgenic plants with resistance to *X. axonopodis* pv. *passiflorae* by expression of the *attA* gene, which encoded for a peptide with bactericide properties. It was verified that either 9.47 μM of hygromycin or 86 μM of kanamycin were sufficient to inhibit organogenesis in 60% of the explants. Transient gene expression was effective when plants were bombarded at 1200 psi of helium pressure and 9.5 cm of distance. Co-transformation frequencies of 0.6% were obtained and transformation was verified by PCR.

Reis *et al.* (2007) analyzed the effect of several factors affecting *A. rhizogenes*-mediated genetic transformation of yellow passionfruit and *P. cincinnata*. Suspension cultures of *A. rhizogenes* strain R1601 were grown in Rhizo medium (Tepfer and Casse-Delbart, 1987) supplemented with 172 μM kanamycin and 269.2 μM ampicillin for 16–18 h at 200 rpm and 28 °C. Bacterial cells were centrifuged and resuspended in MS

medium lacking antibiotics for an OD_{600} of 0.25. Rooted hypocotyl segments were used as explants. The distal portion (4–5 mm) of the hypocotyls was punctured with a hypodermic needle 4–5 times to inject the bacterial cells. Explants were transferred in the upright position to test tubes containing half-strength MS semisolid medium (1/2 MS) lacking growth regulators and B5 vitamins, supplemented with 554 μM myo-inositol and 2% sucrose. The medium was solidified with 0.25% Phytigel and the pH was adjusted to 5.8 before autoclaving. After 20–25 days, hairy roots (1.5–2.0 cm in length) induced by *A. rhizogenes* were detached from the shoots and transferred individually to 30 ml semisolid (0.25% Phytigel) MS medium supplemented with 3% sucrose, B5 vitamins, 554 μM myo-inositol, 264 μM kanamycin, and 817 μM timentin. Transformed roots were subcultured every 15 days to selective fresh medium of the same composition, except that the concentration of kanamycin was increased to 334 μM after the fourth subculture. The first responses were observed 20–30 days after inoculation with *A. rhizogenes*. Hairy roots differentiated at the inoculation sites were used to establish individual root clones and to initiate long-term cultures on semisolid medium. The regenerated roots displayed typical features of hairy roots, including plagiotropism, branching, and growth habit. The *nptII* and nopaline synthase (*nos*) genes were detected by PCR in genomic DNA from root clones of both species at the 6th subculture stage, and the *nos* gene was detected in regenerants derived from somatic embryos of *P. cincinnata*. Physiological confirmation of the transformed nature was provided by the auxin autotrophic response and resistance to kanamycin. Spontaneous plant regeneration from roots growing on selective semisolid MS medium devoid of growth regulators was occasionally observed via organogenesis for yellow passionfruit. *P. cincinnata* displayed higher rates of regeneration, and regenerants were recovered via both organogenesis and somatic embryogenesis.

Alfenas *et al.* (2005) reported the production of transgenic plants of yellow passionfruit expressing an untranslatable RNA corresponding to two-thirds of the replicase (NIb, nuclear inclusion b) cistron and one-third of the adjacent coat protein (CP) cistron of a Brazilian isolate of CABMV. The viral fragment was PCR amplified and cloned into

Figure 3 Construct used for genetic transformation of yellow passionfruit by Alfenas *et al.* (2005); LB, left border of the T-DNA in plasmid pBI121; RB, right border of the T-DNA; Nos pro, Nos promoter, which controls the expression of the kanamycin resistance gene *nptII*; Nos ter, transcription termination signal of the Nos gene; 35S pro, cauliflower mosaic virus 35S promoter, which controls transgene expression; the viral-derived fragment corresponds to two-thirds of the Nib protein coding region and one-third of the coat protein coding region of CABMV isolate MG-Avr

the pBI121 binary vector (Figure 3). Recombinant plasmids were transformed into *A. tumefaciens* strain LBA4404. Genetic transformation of yellow passionfruit was accomplished by co-cultivation of *A. tumefaciens* cells and etiolated hypocotyl segments. The explants were immersed in a suspension of *A. tumefaciens* (OD₆₀₀ 0.4) for 20 min, transferred to nonselective MS medium (3% sucrose, 4.4 μ M BAP, B5 vitamins, 277 μ M myo-inositol, 0.26% Phytigel, pH 5.8) and kept in darkness for 48 h. Transgenic plants were regenerated in selective medium containing kanamycin (264 μ M) and cefotaxime (1048 μ M). After elongation, stems were transferred to rooting medium (1/2 MS, 2% sucrose, B5 vitamins, 277 μ M myo-inositol, 1048 μ M cefotaxime, 5 μ M IAA, 0.26% Phytigel, pH 5.8). Rooted plants were then transferred to substrate. Transformation was verified by PCR for 15 out of 16 R₀ plants. The R₀ plants were vegetatively propagated by cuttings and plants developed from the cuttings were sap-inoculated with CABMV isolates MG-Avr and PE-Bnt. Nontransformed plants developed evident mosaic and leaf deformation symptoms upon inoculation with both isolates. Plants obtained from the R₀-transformant TE5-10 developed the same symptoms upon inoculation with isolate PE-Bnt, but did not show any symptoms upon inoculation with isolate MG-Avr. Viral detection by enzyme-linked immunosorbent assay (ELISA) confirmed the visual observations. The transgenic messenger-RNA (mRNA) was detected in a noninoculated plant derived from the susceptible R₀-transformant TE5-4, but was not detected in noninoculated plants derived from the resistant R₀-transformant TE5-10, suggesting that resistance was due to posttranscriptional (RNA) silencing, which was already activated

in TE5-10-derived plants before inoculation with the viral isolates. Resistance in the hemizygous TE5-10 transgenic plant was, therefore, restricted to isolate MG-Avr. This was explained based on the specificity of RNA silencing (Waterhouse *et al.*, 2001), which requires high sequence identity between the target sequence and the sequence used for transformation (Prins, 2003). The nucleotide sequence identity between the CP cistrons from isolates MG-Avr and PE-Bnt is 93% (Nascimento *et al.*, 2006).

In order to verify whether resistance was stably inherited and dependent on gene dosage, the resistant TE5-10 plant was self-pollinated to obtain R₁ progeny homozygous for the transgene (Nascimento, 2006). Self-pollination was accomplished by covering flowers with a paper bag on the day of anthesis and manually pollinating each flower with a cotton swab, twice (the first time at 1:00 PM, right after anthesis, and the second time at 5:00 PM). Out of 300 attempts, three produced viable fruit, from which a total of 231 seeds were obtained. Fifty-one plants were tested for resistance to three viral isolates (MG-Avr, PE-Bnt, and SE-Nps). Most plants were resistant to MG-Avr, but susceptible to the other two isolates.

One plant, labeled TE5-10-15J, was resistant to all the three isolates, displaying no symptoms after inoculation (Figure 4) and testing ELISA negative. Cuttings were obtained from this plant and the resulting plants were inoculated with an additional four isolates (PB-Alh, BA-Itb, ES-Vni, and PA-Iga), showing an equal level of resistance to all of them. Transgenic mRNA was not detected in clonal plants derived from TE5-10-15J, and viral RNA was not detected in these plants after inoculation with isolates MG-Avr, PE-Bnt, and

Figure 4 Systemic symptoms observed in R_1 transgenic plants following inoculation with CABMV isolates MG-Avr, PE-Bnt, and SE-Nps; NT, nontransformed plant; TE5-10-15J, plant obtained after self-pollination of the R_0 -transformant TE5-10

SE-Nps. The combined results indicated that the TE5-10-15J plant is resistant to at least seven isolates of CABMV from different geographical regions of Brazil, and that resistance is due to RNA silencing, which is already activated before viral inoculation (Nascimento, 2006).

Trevisan *et al.* (2006) reported similar results. The full-length CP cistron from a severe CABMV isolate (referred to as PWV by the authors) was cloned into the pCAMBIA 2300 binary vector, which was transformed into *A. tumefaciens* strain EHA105. *A. tumefaciens* was cultivated in yeast extract peptone supplemented with kanamycin ($172\ \mu\text{M}$) and rifampicin ($60.7\ \mu\text{M}$) for 48 h. Genetic transformation was achieved by inoculation for 20 min of a bacterial suspension (5×10^8 colony-forming units per milliliter) with leaf disks from the Brazilian cultivars “IAC-275” and “IAC-277”. After inoculation, the explants were transferred to MS medium supplemented with TDZ ($1.14\ \mu\text{M}$), AgNO_3 ($23.5\ \mu\text{M}$), and acetosyringone ($100\ \mu\text{M}$) and incubated for 3 days at 24°C . Explants were then transferred to selection medium consisting of MS supplemented with TDZ, AgNO_3 , kanamycin ($172\ \mu\text{M}$), and cefotaxime ($1048\ \mu\text{M}$). Cultures were incubated in the dark for 6 to 8 weeks at 27°C and then changed to a 16-h photoperiod at $27 \pm 1^\circ\text{C}$. Developed shoots were transferred to

Magenta boxes containing elongation medium (MS supplemented with 10% coconut water and $1048\ \mu\text{M}$ cefotaxime), covered with vented lids and incubated with a 16-h photoperiod for further plant development. After transferring to elongation medium, 119 and 109 plantlets of IAC-275 and IAC-277, respectively, were recovered. Transformation was confirmed in seven of eight plants evaluated by Southern blot analysis, showing different numbers of insertional events. Three transgenic plants (T3, T4, and T7) expressed the expected transcript, but the 32 kDa CP was detected by Western blot in only two plants (T3 and T4). The results of three successive mechanical inoculations against the transgenic plants using three CABMV isolates showed that the primary transformant T2 of “IAC-277” was immune to all isolates. Transgenic plants T1, T5, and T8, which showed higher numbers of transgene insertional events than T2, were all susceptible to infection under high inoculum pressure.

3. FUTURE ROAD MAP

3.1 Expected Products

The most-likely short-term development in terms of passionfruit transgenics are woodiness-resistant

plants. The results obtained by Alfenas *et al.* (2005), Nascimento (2006), and Trevisan *et al.* (2006) are promising and indicate that resistance to passionfruit woodiness can be accomplished by expression of untranslatable (Alfenas *et al.*, 2005; Nascimento, 2006) or translatable (Trevisan *et al.*, 2006) virus-derived genomic fragments. The former approach, which is believed to lead to resistance via RNA silencing, provides a high level of resistance, but this is usually of narrow spectrum. Obtaining homozygous transgenic plants is one way to overcome this problem, as shown by Nascimento *et al.* (2006). Resistance to bacterial or fungal diseases is not realistic in the short term, but could become a possibility once a larger number of genes involved in host-pathogen interactions and plant-defense responses are functionally characterized. Other desirable products would be plants with uniform fruit maturity or self-compatible. However, the biochemical pathways that control fruit setting and maturity, as well as self-incompatibility in yellow passionfruit, are likely to involve a large number of genes and have not yet been dissected and therefore such transgenic plants are not likely to be produced in the near future.

3.2 Risks and Concerns

Transgenic passionfruit plants expressing untranslatable constructs of viral origin do not accumulate transgenic mRNA or proteins and therefore offer no risk for human consumption, even considering that passionfruit is consumed fresh. Concerns due to antibiotic resistance genes, which are part of transgenic constructs have been raised, but any real risk remains to be proven. Even then, it is not unrealistic to assume that transgenic passionfruit could be obtained without using selection markers based on antibiotic resistance. In fact, with the transformation efficiency reported in a number of works, transgenic plants could be regenerated without any selectable marker at all. Therefore, risks for human health are negligible or nonexistent.

The losses caused by passionfruit woodiness are so dramatic and widespread that growers' demand for resistant plants, whether obtained by conventional breeding or engineered resistance, is high. In this context, it is safe to assume that,

once transgenic plants resistant to the disease are available, growers will rapidly adopt them (public opinion issues aside). The possibility exists, therefore, for large-scale planting of one or two yellow passionfruit cultivars, thus severely reducing the genetic basis of the crop. Different alleles to guarantee the compatibility among the orchard plants are also necessary due to the presence of an auto-incompatibility system, as previously mentioned. Such scenario is well known to generate the risk of new epidemics of previously secondary diseases, if the new cultivars are specially susceptible to them. It is important to assure that a number of genetically diverse materials be transformed and made available to growers. Considering that all work carried out to date (at least in Brazil) was done at public institutions, the possibility exists for the free exchange of information and materials among researchers, reducing overhead costs and benefiting the entire passionfruit production chain.

The most difficult issue to be addressed with passionfruit transgenics is certainly gene flow towards wild *Passiflora* species and especially towards commercial fields of nontransgenic yellow passionfruit. As mentioned in Section 1.1, more than 150 species of *Passiflora* are native to Brazil. Very little is known about the actual possibilities of gene flow among different species, so the actual risk is difficult to be assessed. However, it is quite likely that yellow passionfruit pollen can fertilize the flowers of other species, even if at low efficiency. On this regard, further research is necessary to verify the outcrossing rate of different *Passiflora* species and the fertilization efficiency of yellow passionfruit pollen in those species. Gene flow towards nontransgenic yellow passionfruit will be essentially dependent on the insect pollinator, since pollination by wind is negligible. It is generally assumed that carpenter bees have an effective range of 1–3 km, but there is no data on the effective pollination efficiency as a function of distance.

The potential for gene flow in yellow passionfruit was studied by Torres (2003). An experimental plot with 2640 m² was established, consisting of four rows of plants with 210 m each, 3 m apart. Each row consisted of 23 yellow passionfruit plants, planted at 10 m intervals. At one end of each line, four distinct genotypes were planted, and the remaining of each line was planted with clones from the same plant

of a fifth genotype. Due to self-incompatibility, pollination along each line would only occur with pollen from the plants located at the end of each line, carried by the insect pollinator (a study of pollen dispersal from a single plant by wind was also carried out, and the results indicated that gene flow mediated by wind dispersal of pollen does not take place at distances greater than 3 m). Viable fruit were produced in the plants located at the maximum measured distance of 210 m, indicating that gene flow mediated by the pollinator insect could take place at that distance. A decrease in the percentage of pollination along the lines was observed, however, the trend was not statistically significant using either parametric or nonparametric models. It is necessary to test greater distances, preferably in the km range, in order to determine the minimum distance between fields of transgenic and nontransgenic plants to avoid undesired gene flow.

ACKNOWLEDGMENTS

Research at the authors' laboratories has been funded by Fundação de Amparo à Pesquisa do Estado de Minas Gerais (FAPEMIG), Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP), and Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq).

1. INTRODUCTION

1.1 History, Origin, and Distribution

The word “persimmon”, used by the Algonquin Indians of Virginia, indicates at least two fruit tree species, with different history, diffusion, and use. One of them, originated in Asia, is Oriental or Japanese persimmon, Kaki or the “apple of the Orient” (botanically named as *Diospyros kaki* L., *Diospyros kaki* L.f., or more precisely *D. kaki* Thunb.). It is by far the most important *Diospyros* for fruit production. The other, known at present as common persimmon, is *Diospyros virginiana* L. of American origin, a relative of *D. kaki*. It is used as a secondary species for fruit production and also as rootstock for Oriental persimmon in some cultivation areas (Yonemori *et al.*, 2000). This chapter is devoted to *D. kaki* and hereinafter its common name “kaki” will be used all along the chapter.

There are no paleobotanical studies on the history of domestication and diffusion in the past of kaki. It is believed to have a Chinese origin, since its wild types abound and a wide range of variability in many traits such as fruit color, shape, sepal duplication, has been observed in temperate areas of China (Wilson, 1929; Grubov, 1967). Kaki, originated in ancient times, has been cultivated for centuries only within its birthplace and in the neighborhood (Sugiura, 1997). Kaki cultivars

are known in China since the Tang dynasty (Li *et al.*, 1996; Wang *et al.*, 1997a, b) and the most ancient records of descriptions of kaki are in Chinese (Kikuchi, 1948). Early in the 14th century Marco Polo recorded that the Chinese used to trade in kaki (Morton, 1987). Hence, China is considered the primary center of diversity (Zheven and Zhukovsky, 1975). Kaki passed from China to the next temperate areas, namely, Japan in the 7th century and Korea in the 14th century, which can be considered secondary centers of diversification. An ancient record regarding the presence of kaki in Japan is reported in the Honzo-Wamei, the oldest encyclopedia of herbs published in 918 and the first Japanese description of a kaki cultivar, “Zenjimarū”, is dated 1241. Korea has old ceremonies that feature the kaki and many local varieties are known in traditional fruit culture (Kang and Ko, 1997). Kaki trees have been grown in Vietnam, Indonesia and the Philippines since a long time (Morton, 1987). Kaki cultivars were introduced in India by the Europeans only in 1929 (Mehta *et al.*, 2005). Now most of the Asian countries including Nepal, Pakistan, and Thailand cultivate kaki.

Records on the presence of kaki in the Mediterranean basin are few. Pliny the Elder (24–79) in the *Historia Naturalis* wrote that “lotus trees in the Piazza del Tempio and by the Temple of Vulcano, well known for the development of

shoots and for the nice shade they produced” were present in ancient Rome. Kaki is called in Italy and Greece also as “loto”, word used also for *Diospyros lotus* L., a relative of kaki of eastern, central and western Asiatic origin. No records are available regarding the presence of kaki in Europe during Medieval and Renaissance periods. Ricci, a Jesuit Monk who traveled to China, mentioned this species in 1613 (Evreinoff, 1948) and kaki was quoted by Trigault in 1615, nevertheless for De Candolle (1778–1841) both *D. kaki* and *D. lotus* were not yet well known species (Occhialini and Tirocco, 1923). In 1860, kaki trees were imported into France (Occhialini and Tirocco, 1923; Morettini, 1949) and 10 years later its cultivation developed in Provence and other Mediterranean French areas, passing to Italy in 1871–1876 and to Algeria in 1984 (Evreinoff, 1948; Morettini, 1949). The appearance of kaki in Spain dates to the end of the 19th century (Climent and Llácer, 2001), even an earlier introduction could have been possible, taking into account the strong relationships between that kingdom and Oriental countries during the colonization period. In Greece and Portugal, kaki may have been present for a relatively long time (Morettini, 1949). The introduction of kaki in Balkan countries seems to have taken place later, middle of the 20th century. *D. kaki* and *D. lotus* were introduced from Russia, where appeared in 1888 (Evreinoff, 1948), to Turkey (Tuzcu and Seker, 1997). In the 20th century the main areas of cultivation in Europe and in the Mediterranean basin were located in Italy, Spain, Israel, Greece, Portugal, Egypt, France, and various countries of the former Yugoslavia, Cyprus, and Morocco.

In North America, kaki was introduced in 1856, when seeds were sent from Japan by Commodore Perry. In 1870 grafted trees were imported by the US Department of Agriculture and distributed to California and the southern states. In the period 1911–1923, other propagation material of kaki were introduced in the United States and plants were sent also to Arizona, Texas, Louisiana, Mississippi, Georgia, Alabama, Southeastern Virginia, and northern Florida (Morton, 1987). Kaki is also cultivated in Mexico. In South America, kaki was introduced in Brazil from France in 1890 as seeds sent by the naturalist Charles Naudin to São Paulo (Picarelli and Mendes, 1989) and then by Japanese immigrants;

the cultivation spread to many states, such as São Paulo, Rio Grande do Sul, Parana, Rio de Janeiro, Minas Gerais, Ceará, Pernambuco, Piauí, Bahia (Morton, 1987). Kaki is also present in Argentina and Chile. Kaki was introduced into Queensland, Australia, around 1885 and then it passed to New South Wales. In 1873, kaki was introduced into New Zealand from Japan.

Hence, kaki has been gaining in popularity worldwide. It is called “kaki” in Japan and most of European countries, “shi” in China, “gam” in Korea, and “persimmon” in Australia and New Zealand. Sharon fruit in the United Kingdom is a trademark name, exclusively reserved for “Triumph” kaki grown in Israel.

1.2 Botanical Description

About 400 species belong to the genus *Diospyros* in the family Ebenaceae, which consists of the two genera, *Euclea* and *Diospyros*, in the order Ebenales. Most of them are of tropical and subtropical origin (Cronquist, 1981; Ng, 1986), but the most common species of temperate climate are *Diospyros kaki* Thunb., often reported as *D. kaki* L. or *D. kaki* L.f., and the relatives *D. lotus* L., *D. oleifera* Cheng, and *D. rhombifolia* Hemsl. All of them have Asian origin, but *D. virginiana* L. is originated from North America. As for fruit production, *D. kaki*, *D. lotus*, *D. oleifera*, and *D. virginiana*, are important, and there are some minor important species, such as *D. digyna*, *D. discolor*, and *D. texana*. The most important species is undoubtedly kaki, *D. kaki*. *D. lotus*, date plum, was known to the ancient Greeks as “the fruit of the Gods”, that is, *Dios pyros*, hence the scientific name of the genus. Date plum is native to Southwest Asia and Southeast Europe, and used as a fruit in Asia and as a rootstock for kaki in China, Israel, Italy, Japan, and the United States. *D. oleifera* is grown in China mainly as a source of tannin and thought to be a parent of *D. kaki* (Ng, 1978). *D. virginiana*, American persimmon, grows wild but has rarely been cultivated. The name “persimmon” comes from “putchamin”, a phonetic rendering of the name used by the Native Americans. *D. rhombifolia* is a bushy plant of Chinese origin, rarely used as a rootstock for kaki, and used as a bonsai, a potted dwarfed tree, in Japan.

Kaki is a single-stemmed (sometimes multi-trunked) deciduous long-living tree, and tends to become a large tree. For example, a huge old tree growing in the Okayama prefecture in Japan is estimated to be 400 years old, has a trunk circumference of 4.5 m, is 17 m in height, and is grafted onto a seedling stock. The trunk is upright and the bark is dark gray, with many irregular cracks. The branches are generally upright, winding and often fragile. One-year shoots are brown or gray, with many pale lenticels, and they are upright or winding. Flowers and then fruits are brought by twigs. The root is pivot and very deep. Kaki leaves are alternate, simple, ovate or obovate. The size varies with the cultivar from 50 cm² to over 200 cm². The edge is winding and the margin is entire. Kaki leaves are often pale green in youth, turning a dark, glossy green as they grow. In autumn, most of them tinge yellow, orange or red before falling.

The flowers are borne in the leaf axils of new shoots originated from a flowering bud of 1-year-old shoots. Kaki has a complex sex expression, since trees can bear separately or together female (pistillate) flowers, male (staminate) flowers and complete (hermaphrodite) flowers, being classified as polygamous dioic. The commercial cultivars exhibit three types of sex expression, those that bear: (1) only pistillate flowers (pistillate type), (2) both pistillate and staminate flowers (monoecious type), and (3) hermaphroditic flowers in addition to pistillate and staminate flowers (polygamomonoecious type) (Yonemori *et al.*, 1993). Female flowers are solitary, larger than male flowers, with yellow-whitish small petals, borne by a green calyx. Male flowers are borne in clusters formed by three small flowers, the central flower being occasionally hermaphrodite. Fruits derived from hermaphrodite flowers are very small with no commercial value. Pollination is carried out by insects, mostly by honey bees, but fruits can be obtained by parthenocarpy. Parthenocarpic fruits are seedless and are preferred by consumers. However, in practice, pollination is desirable to reduce natural fruit drop and improve fruit quality such as size and shape. Hence, commercial orchards in Japan are planted with pistillate-type cultivars and are interplanted with monoecious types as pollinizers. In Italy and Spain, where soft fruits are consumed and the main cultivated varieties (“Kaki Tipo” and “Rojo Brillante”) are

astrigent and very productive by parthenocarpy, seedless fruits are preferred and pollinizers are not desired. Pollinizers are used in Southern Italy in order to obtain hard edible fruits on pollination of variant nonastrigent types (e.g., “Kaki Tipo”).

The fruit is a big berry showing wide variation in size, from 50 g to over 500 g, shape, from acorn to flat to spherical or square, in skin color, from light yellow-orange to dark orange-red or black purple, and in flavor. The 8 ovary lodges, which can bear from none to one seed in each, can be seen in cross-section. The flesh color varies from orange yellow, and sometimes reddish, to reddish brown or bronze depending on the astringency at harvest time and on presence of seed in the fruit.

The most relevant trait by which kaki cultivars are classified is astringency of fruits at harvest time (Yonemori *et al.*, 2000). All cultivars of kaki produce edible fruits when they are jelly soft, i.e., when they are over-ripe; but at harvest time (when fruits are still firm) kaki can be astrigent (not edible) or nonastrigent (edible) depending on the cultivar. Astrigent and nonastrigent types are divided into two subgroups: variant and constant type, depending on the effect of presence of seeds on flesh color. In variant types flesh color changes to dark when pollination of female flower occurs and seeds are present in the fruit, while in constant types flesh color is not affected by presence of seeds (Hume, 1913, 1914). Hence, kaki cultivars are divided into four groups: pollination constant nonastrigent (PCNA); pollination variant nonastrigent (PVNA); pollination variant astrigent (PVA); and pollination constant astrigent (PCA) (Kajiura, 1946). From the group names, it seems that pollination is important, but it is the seeds, not pollination *per se* that influence the fruits. Changes in fresh color and astringency are related to seed formation rather than pollination. At harvest time, PCNA type loses astringency regardless the presence of seeds, hence parthenocarpic seedless hard fruits can be easily handled, transported and marketed; PVNA cultivars bring edible hard and dark fleshed fruits at harvest only when pollination occurs and there is a high number of seeds. PCA and PVA cultivars have astrigent fruits at harvest time, regardless the presence of seeds: PVA fruits with seeds have a dark flesh only next to the seeds. Hence fruits with or without seeds of PCA and PVA cultivars and parthenocarpic seedless fruits of PVNA cultivars, are astrigent at harvest,

and they become edible after artificial removal of astringency or when fruits are overripe. The difference in the cessation of tannin accumulation in fruit, the tannin characteristics (Sugiura *et al.*, 1979; Yonemori *et al.*, 1983; Yonemori and Matsushima, 1987a, b) and the ability of seeds of producing volatile compounds (Sugiura *et al.*, 1979; Sugiura and Tomana, 1983) are under a new classification suggested by Sugiura (1984). He divided kaki cultivars into volatile independent group (VIG) (corresponding to the PCNA type) and the volatile dependent group (VDG), which includes PCA, PVA, and PVNA types.

Astringency is caused by water-soluble tannins, which are found in large special cells, tannin cells, in the fruit flesh. In pollination variant cultivars, seeds exude acetaldehyde, which causes the soluble tannins to be condensed or coagulated and to become insoluble and oxidized: as a result, many brown specks, denaturalized tannin cells, are formed in the flesh, and the flesh color darkens. The seeds of PVNA type exude so much that the fruit becomes nonastringent, but those of PVA exude so little that the fruit is still astringent and those of PCA did not exude it. These fruits can only be eaten firm after the astringency has been removed artificially, for example, by carbon dioxide gas or ethanol treatment. Tannin cells in PCNA type ceases developing at an early stage of fruit development, while tannin cells of other types continue to develop. PCNA vs. non-PCNA is qualitatively inherited. The trait of PCNA of Japanese origin is recessive to that of non-PCNA. Recently, the trait of PCNA of Chinese origin has been suggested to be dominant over that of non-PCNA (Yamada, 2006).

PCNA pomological group, characterized by cultivars with late ripening time, low productivity by parthenocarpy, high susceptibility to physiological disorders (calyx separation and apex breaking), more exigent in terms of mild Autumns, low affinity to grafting on *D. lotus*, presents a narrow genetic variability in respect to PVNA type: in China and Japan the amount of PCNA cultivars is by far inferior to astringent type (Yonemori *et al.*, 2000, 2005).

In Japan the evolution of PCNA is geographically limited to central Japan (Yamada, 1993) and it appears to be quite recent, being "Gosho" the first PCNA to be documented in the 17th century (Kikuchi, 1948), while in 1214

a record of a PVNA cultivar, "Zenjimaru", was found in Japan. Furthermore, 40 PCNA cultivars collected in Japan were grouped into 17 clusters by means of isozyme marker analysis and most of these cultivars were bud mutations of common ancestors, showing very similar morphological traits (Sugiura *et al.*, 1990). The narrow genetic variability of PCNA group in Japan has been confirmed by means of amplified fragment length polymorphism analysis (Kanzaki *et al.*, 2000) and by progeny tests of PCNA \times PCNA crosses, where lethal genes and inbreeding depression have been often observed (Bellini and Giordani, 1998; Yamada, 2005). The evolution of PCNA cultivars in China seems to be precedent, since "Loutian Tianshi" was cultivated for over 900 years; as in Japan, the known PCNA cultivars and strains (about 8 varieties, among which "Loutian Tianshi") developed in a narrow geographical area in Hubei province (Wang *et al.*, 2005; Yonemori *et al.*, 2005). The PCNA cultivars ("Daeon Dangan" and others) presumed to be native to Korea appear to be Japanese cultivars (Yonemori *et al.*, 2000; Park *et al.*, 2005). All varieties of presumed origin in the Mediterranean Sea area belong to astringent type (Giordani, 2002).

Kaki can be considered a species for warm-temperate areas, even if among cultivars there exist many different behaviors in acclimatization. It is moderately resistant to winter frost (tolerating winter temperatures of -15°C), but sensitive to late spring chill and to strong winds mainly during summer and autumn when the weight of fruits can brake the shoots and the fruits can be injured by rubbing. The best soils to grow kaki are those of medium texture, deep and fresh, but this species can grow also on clayey soils. Subacid and subalkaline soils and active limestone soils are good for kaki, while salty soils and those rich in boron should be avoided.

Wild type *D. kaki* is reported to exist in Chinese forests (Wilson, 1929; Grubov, 1967). Phylogenetic studies on chloroplast DNA between kaki (*D. kaki*) and other temperate and tropical *Diospyros* species, indicated that *D. kaki* seems to have a common ancestor with *D. lotus* and *D. virginiana* (Yonemori *et al.*, 1998) and to be closely related to *D. ehretioides* and to *D. oleifera* as was previously indicated by restriction fragment length polymorphism analysis of mitochondrial DNA by Nakamura and Kobayashi (1994), while

D. glandulosa (= *D. roxburghii*) appears more distant despite the observations of Ng (1978) on the basis of morphological similarity and geographical distribution. Recently, Choi *et al.* (2003) investigated genomic similarity among *D. kaki* and nine closely related to distant *Diospyros* species analyzing repetitive DNAs isolated from *D. kaki*, *D. oleifera* and *D. ehretioides*. Repetitive DNA (restricted with *EcoRV*) was present in five closely related species (*D. kaki*, *D. lotus*, *D. glandulosa*, *D. oleifera*, and *D. virginiana*) while *HindIII*-digested repetitive DNA was also found in those species, except for in *D. virginiana*, suggesting that different ancestral species might have been involved in the speciation of *D. virginiana* and *D. kaki*, as was also indicated by Nakatsuka *et al.* (2002) analyzing Ty1-copia group retrotransposons. In the same work, Choi *et al.* (2003) found a very close relationship between *D. kaki* and three diploid *Diospyros* species (*D. glandulosa*, *D. oleifera* and *D. lotus*), confirming the results obtained by Yonemori *et al.* (2008) from studies on the sequences of the internal transcribed spacer and *matK* regions. Such species could have been involved in the speciation of *D. kaki*, which can be an autohexaploid or autoallohexaploid, as suggested also by the observation of segregation pattern of a molecular marker linked to astringency loss (Kanzaki *et al.*, 2001) and four sets of chromosomes carrying 45s ribosomal DNA (Choi *et al.*, 2003).

The somatic chromosome number of *D. kaki* Thunb. is 90 ($2n = 6x = 90$) (Namikawa and Higashi, 1928). But recently, Zhuang *et al.* (1990, 1992) reported the existence of nonaploid cultivars such as “Hiratanenashi”, “Tone Wase”, “Miyazakitanenashi”, and “Watarizawa”, all of them producing generally seedless fruits. The base chromosome number of genus *Diospyros* is presumed to be $x = 15$, and *D. lotus* and *D. oleifera* are diploid ($2n = 30$), *D. rhombifolia* is tetraploid (Zhuang *et al.*, 1990) and Baldwin and Culp (1941) indicated that *D. virginiana* presents two karyotypes ($2n = 60$ and 90). Ploidy variation was observed in kaki progenies of “Fujiwaragoshō” cultivar (Tao *et al.*, 2003); nonaploid plants were obtained by artificial hybridization of hexaploid cultivar with natural unreduced $2n$ pollen (Sugiura *et al.*, 2000); heteroploidy was observed on embryos obtained from poorly filled seeds of the cultivar “Maekawa Jiro” (Hasegawa *et al.*, 1997).

The genome sizes established by flow cytometry for hexaploid and for nonaploid cultivars of kaki were estimated to be 5.00–5.24 pg/2C and 7.51–8.12 pg/2C, respectively (Tamura *et al.*, 1998b); while nuclear DNA contents of *D. virginiana* and of *D. rhombifolia* were 5.12 and 3.76 pg/2C.

1.3 Economic Importance

Kaki has been mainly grown in China, Japan, and Korea. In China, it is one of the most popular fruit crops, and both of the acreage and production ranked first in the world and 9th in China mainland comparing with other fruits (Luo *et al.*, 2005). In Japan, it was the primary fruit crop for a long time, and even today it ranks 4th in production after satsuma mandarin, apple, and pear (Yamada, 2006). In Korea, the cultivation area in 2004 ranked first comparing with other fruits. However, official data on the area coverage and production of kaki all over the world are not easily available. FAO Statistics indicates a world production in 2005 of 2 561 732 t on an area of 730 592 ha, with a positive trend since 1965 (Figure 1). In FAO statistics only 10 countries are listed as kaki producers: China (1 837 000 t), Korea (250 000 t), Japan (230 000 t), Brazil (67 000 t), Italy (50 000 t), Israel (40 000 t), then New Zealand, Iran, Australia, and Mexico with about 1000 t (Figure 2) (FAO, 2006). A main gap regards Spain, where the kaki industry strongly developed in the last 15 years, production for 2005 is estimated in 43 750 t (M.L. Badenes and G. Llacer, personal communication). Chile produced 1300 t from 146 ha in 2005 (ODEPA, 2006). Other countries producing kaki in the Mediterranean basin are Turkey, Greece, Portugal, Cyprus, Slovenia, Montenegro, Albania, Egypt, Macedonia (FYROM), and Czech Republic (for a total estimated production of 30 000–40 000 t). Other countries interested in the cultivation of kaki are Morocco, South Africa, Thailand, Malaysia, and Argentina. The Californian production in 1965 amounted to 2100 t. In 1970, California produced 1600 t, about 92% of the total US crop (Morton, 1987). World production of kaki is increasing. Kaki international trade is quite limited; the main exporters are Israel, Spain, Italy, New Zealand, Australia, and Korea, while the

Figure 1 Evolution of kaki production and area coverage (years 1965–2005) (Source: FAO, 2006)

importers are Singapore, Thailand, Hong Kong, Brazil, Germany, Swiss, the United Kingdom, and Belgium; the mean value of exported kaki was US\$1277/t (FAO, 2006).

Kaki is a highly nutritional fruit containing carotenoids, vitamin C, tannins, pectic substances,

and high levels of sugars (Ito, 1971). The sugar content is 14–18 g/100 g fresh weight, fructose and glucose (45% each one on the total) being the most important, while sucrose (generally not present at ripening time), galactose and arabinose are minor components. The total amount of

Figure 2 Kaki production (% on the total) by countries in the year 2005 (Source: FAO, 2006)

pectic substances ranges from 0.7% to 1.0% in fresh weight. The amount of soluble tannins ranges from 0% to 4% in fresh weight depending on the cultivar, and of the ripening stage, a leucodelphinidin 3-glucoside named “diospyrin” being the main tannin, while minor components are leucocyanidin, gallic acid, galocatechin, and galocatechin gallate. The total amount of carotenoids ranges between 5 and 6 mg/100 g in fresh weight (10 times higher in the peel): β -cryptoxanthin and lycopene are the major components and β -carotene is also present in small amounts. Kaki is a good source of vitamin C (about 50 mg of ascorbic acid per 100 g of fresh pulp) (Souci *et al.*, 1990). Nineteen amino acids are identified in the flesh, citrulline being the main component. The amino nitrogen is about 15 mg/100 g fresh weight (Testoni, 2002). Kaki is an interesting nutraceutical fruit because of its high amount of carotenoids and polyphenols: β -carotene, lycopene, and β -cryptoxanthin regulate the activity of lipoxygenase in human being, which is responsible for the production of proinflammatory molecules. Tannins have a protective role against free radicals. There have been suggestions that kaki is also beneficial in reducing high blood pressure and has antibacterial effects (Testoni, 2002). Fractioned extracts of kaki peels showed potential antitumor and multidrug resistance reversal activity (Kawase *et al.*, 2003).

Most of kaki production is consumed as fresh fruits (soft or hard) for dessert, but dried fruits are also used mainly in oriental countries and in Europe. Dried fruit is also used for sweetening in various cuisines and confectionary in oriental countries. In Korea, a punch is made from dried kaki. In China and Japan, dried kaki leaves are used for tea. The mushiness and chemical composition (namely, the low content of organic acids) of kaki hinder the industrial preparation of jam. However, fruit can be transformed into juices, mousses, frozen puree for ice cream preparation, alcoholic beverages and its distillates. In Korea, unripe fruit is used for dyeing of garment; in Japan kaki tannin extracted from young fruit has long been used as an antiseptic or water proof for paper used for umbrellas and for fishing fiver nets. Kaki tannin has also been used as a medicine and cosmetic. For traditional Japanese dishes, amber vinegar made from kaki fruit has been used as a flavoring and autumnal red leaves has been used

as a garnish on a dish. Kaki woods are hard and solid enough to be good material for furniture, ornaments, and the head of golf club.

1.4 Traditional Breeding

The perception of quality in kaki for traditional consumers is commonly referred to fruit hardness at consumption, taste, color of skin and of flesh, and presence of seeds, while ripening time can be considered as a marketing requisite. On the other hand, kaki farmers are eager to get a new cultivar with cold, drought, frost, pest, and disease resistances or with higher productivity. In last years, fruit quality has included also nutraceutic characteristics (e.g., vitamin content), healthiness perceived as absence of pesticide (e.g., amount of residues), and environment friendly production (e.g., organic farming, integrated pest management, etc.).

Two types of kaki fruit can be eaten fresh: hard and soft fruits. Hard fruit (i.e., as apple) is produced by PCNA type with or without seeds and by PVNA type with many seeds. Soft and generally seedless fruit, which are consumed overripe, are produced by PCA and PVA with or without seeds and PVNA without seeds. Firm edible fruit can also be obtained by artificial removal of the astringency of non-PCNA types with carbon dioxide or ethanol at harvest, but their eating quality, flesh color and shelf-life are often inferior (Kitagawa and Glucina, 1984; Testoni, 2002) and the work requires much labor, time, and expensive facility for mass production. Hence the evolution of kaki industry and marketing in the last decades, together with handling and transport requirements, and consumer's preference to eat hard fruits, led to consider PCNA cultivars the preferred type (Yonemori *et al.*, 2000; Giordani, 2002).

Hence, the main breeding objective is to obtain PCNA cultivars bringing valuable general characteristics (superior to “Fuyu” and “Jiro”, the leading PCNA cultivars in Japan) such as early ripening time (to broaden market period and to avoid autumn frost injuries during ripening time); high eating quality (high sugar content, juicy and soft melting or crisp flesh); seedless or high and constant productivity by parthenocarp; large fruit with round shape, no physiological disorders

(apex cracking and calyx separation); attractive flesh color (brilliant orange-reddish color); long shelf life and resistance to the most common pests (fruit fly in Mediterranean countries, bark borers, etc.) and diseases; adaptability to different environments (Yonemori *et al.*, 2000; Giordani, 2002; Yamada, 2005). Taking into account kaki propagation, most of the cultivars and rootstocks are recalcitrant to *in vivo* and *in vitro* rooting, hence no self-rooted cultivar or homogeneous rootstock are available. Rootstocks are obtained from seedlings of *D. kaki*, *D. lotus*, and *D. virginiana*, hence their characteristics (such as tree vigor, frost resistance, etc.) are not the same as those of the mother plant. High rooting ability of cultivars and/or rootstocks and cultivar compatibility with *D. lotus*, the main rootstock used in Europe, are also desired characteristics. In Italy and Spain, where “Kaki Tipo” and “Rojo Brillante”, two astringent varieties, are extensively cultivated, a breeding objective is also to obtain high quality, high productive early ripening non-PCNA cultivars (Giordani, 2002). Similar objectives are sought in Korea, where new non-PCNA cultivars with juicy fruits, early ripening, red-ripe soft kaki, suitable for vinegar production and high-quality “Sangjudoongsi” clones are desired (Song *et al.*, 2005). In Japan, a non-PCNA fruit with larger, longer shelf life and better taste is one of the breeding objectives.

The oldest kaki breeding program has been carried on since 1938 in Japan, while other countries involved in kaki breeding were (or still are) China and Korea in Asia, and Brazil, Italy, Spain, Israel, and former Soviet Union (Bellini *et al.*, 1998; Giordani, 2002; Yamada, 2005). The main strategies applied were the selection of superior genotypes within local germplasm (ancestral cultivars and their bud mutations) and intraspecific cross-breeding (recurrent selection and backcross) (Yonemori *et al.*, 2000; Giordani, 2002; Song *et al.*, 2005; Yamada, 2005) and interspecific hybridization (Pasenkov, 1974).

Selection of superior genotypes was carried out mainly in the center of origin (China) and centers of diversification (firstly Japan and Korea, and in more recent times in the United States, Italy, and Spain) (Yonemori *et al.*, 2000). Selection was based on comparative evaluation of morphological characteristics among the collected accessions. In China, 550 genotypes belonging

mostly to the Chinese native germplasm have been collected and evaluated for resistance traits by the National Fruits Germplasm Repository for kaki and 110 accessions, among which Chinese PCNA cultivars are collected in the kaki repository Huazhong Agricultural University (Luo *et al.*, 2005). In Japan, 263 local accessions are listed and widely described by the National Institute of Agrobiological Sciences (NIAS) GenBank (NIAS, 2006) and about 600 genotypes are collected at NIFTS, Akitsu, Hiroshima (Yamada, 2005). In Korea, 233 local cultivars were collected during 1959–1969 at the Experimental Station at Kim-hae (Yonemori *et al.*, 2000); many local varieties from different areas have been morphologically described and a recent survey has been carried out at Jeju Island (Park *et al.*, 2005). By the USDA-ARS National Clonal Repository, few *D. kaki* of Japanese origin are collected together with *D. lotus* and *D. virginiana* accessions (USDA, 2006). Many of the accessions collected in Asia have been analyzed by molecular markers in order to assess distinctness and to study genetic relationships (Yonemori *et al.*, 2000). In Europe, 161 genotypes were collected by national or regional repositories of Italy and Spain, including accessions of presumed local origin, among which “Kaki Tipo” and other PVNA varieties, and “Rojo Brillante”, “Cristalino”, “Picudo”, “Tomatero”, “Xato del Bon Repòs” among others in Spain (Giordani, 2002). Most of the accessions belonging to the European collections have been morphologically described and genetically characterized for distinctness by means of random amplified polymorphic DNA markers (Bellini, 1982; Badenes *et al.*, 2003; Bellini *et al.*, 2003). Other European countries that are developing kaki collections are Romania (11 accessions) and the Czech Republic (28 collected accessions) (Bellini and Giordani, 2005). Turkey holds several collections for a total of 74 accessions (Tuzcu and Seker, 1997).

The problem of cultivar distinctness and identification, far to be solved, did not hinder the activity of selection in collected accessions of kaki taking into account morphological characteristics. The main achievements obtained by preferential selection of superior genotypes within native germplasm and their bud mutation (namely, in the center of origin and in the close diversification areas) are reported in Table 1 together with

Table 1 Superior cultivars obtained by selection from local germplasm and spontaneous bud mutations

Cultivar name	Type	Country	Genetic origin and/or characteristics
Anguyoushi	PCA	China	Big fruit, juicy
Dahongshi	PCA	China	Juicy
Tone Wase, Spur-hiratanenashi, Sugita Wase, Oh-tanenashi, Kohshimaru	PVA	Japan	Bud mutations of “Hiratanenashi”, with different improving characteristics (earlier ripening time, bigger fruits, higher productivity)
Aichi Wase Fuyu, Matsumoto Wase Fuyu, Uenishi Wase, Tanba Wase Fuyu	PCNA	Japan	Bud mutations of “Fuyu”, with different improving characteristics (earlier ripening time, better taste)
Maekawa Jiro, Ichikikei Jiro, Aisyuhou	PCNA	Japan	Bud mutations from “Jiro”, earlier ripening time, better fruit skin color
Kaki Tipo	PVNA	Italy	Uncertain origin, perhaps “Amahyakume” from Japan; big fruit, high eating quality, high productivity, medium late-ripening time
Mercatelli, Moro, Vainiglia	PVNA	Italy	Uncertain origin, perhaps “Zenjimarū” from Japan; male flowers, medium fruit size, good taste; very high parthenocarpic productivity
Rojo Brillante	PVNA PVA (?)	Spain	Mutation of “Cristalino”; big fruits, high flesh quality; attractive peel and shape, very high parthenocarpic productivity

results obtained from presumed local germplasm of European countries, Italy and Spain. Most of the reported varieties are widely cultivated in the countries of origin and abroad (namely, the Japanese PCNA cultivars, “Fuyu” and “Jiro”), nevertheless the variability that they exhibit is not enough to ensure a sound development of kaki industry and to improve many undesirable traits (such as late ripening time, susceptibility to physiological disorders, astringency at harvest time, etc.) borne by these cultivars (Bellini *et al.*, 1998; Yonemori *et al.*, 2000; Giordani, 2002; Yamada, 2005).

Cross-breeding is the main strategy adopted in recent times to obtain high value cultivars. Breeding programs started in 1938 in Japan, and in the second half of 20th century in Korea, Brazil, Italy, Israel and former Soviet Union, while in 2005 a Spanish breeding program started at Valencia (Bellini *et al.*, 1998; Yonemori *et al.*, 2000; Song *et al.*, 2005; Yamada, 2005; M.L. Badenes and G. Llacer, personal communication).

Crossing protocols are quite simple, since pistillate flowers are big and receptive, pollination is easy (often the small staminate flowers are just rubbed on the pistil of female flowers), fruit set ratio is high and up to eight seeds can be obtained per fruit; after stratification, germination rate of seeds is generally high. Taking into account other temperate fruit tree species, showing a long juvenile

unproductive phase, kaki seedlings bear flowers 3–5 years after germination (Bellini *et al.*, 1993). Furthermore, molecular marker-assisted selection has been developed for the trait non-PCNA (Kanzaki *et al.*, 2000, 2001) and it will be used for early selection and grafting of PCNA seedling for promoting early fruiting (Yamada, 2005).

The main results achieved in terms of released cultivars are reported in Table 2. At present, none of the new kaki cultivars obtained by cross-breeding has been widely cultivated. Only few of them represent a small percentage of the whole production, for example “Taishu” in Japan (100 ha in 2003) (Yamada, 2006), and varietal assortment of kaki appears to be rather static in comparison with other fruit tree species (e.g., apple, peach and citrus) where outstanding new released cultivars are immediately grown and they supplant old fashioned cultivars (Yonemori *et al.*, 2000; Giordani, 2002; Yamada, 2005).

Progeny tests carried out in the last 50 years in Japan improved knowledge about inheritance in kaki (Yamada, 2005). Among them, the hereditary behavior of loss of astringency at harvest time is outstanding, given its relevance in cross-breeding.

The studies of Ikeda *et al.* (1985) demonstrated that the trait regulating astringency at harvest is qualitatively inherited, PCNA being recessive to non-PCNA. PCNA F₁ progenies can be obtained only crossing PCNA types, since ancestral

Table 2 Kaki cultivars obtained by cross-breeding release

Cultivar name	Country	Genetic origin	Type	Year of release	Main characteristics
Kaoru	Brazil	—	PVA	—	Big fruit
Suruga	Japan	Hana-gosho × Oku-gosho	PCNA	1959	Big fruit, late ripening, fruit cracking, not juicy
Nishimura Wase	Japan	Fuyu × Akagaki (very improbable)	PVNA	1960	Big fruit, male flowers, early ripening
Izu	Japan	Fuyu × A4 (Oku-gosho × Oku-gosho)	PCNA	1970	Good taste and color; low productivity, weak tree, early ripening
Rossiyanaka	Former Soviet Union	<i>D. kaki</i> × <i>D. virginiana</i>	Astringent	1974	Small fruits, astringent flesh, resistance to frost
Tavrichanka	Former Soviet Union	<i>D. kaki</i> × <i>D. virginiana</i>	Astringent	1974	Small fruits, astringent flesh, resistance to frost
Zvezdochka	Former Soviet Union	<i>D. kaki</i> × <i>D. virginiana</i>	Astringent	1974	Small fruits, astringent flesh, resistance to frost
Fuyu Hana	Brazil	Fuyu × Hana-gosho	PCNA	1984	Large fruits, male flowers, seeded fruits
Pomelo	Brazil	—	PCA	1985	Big fruit, early ripening time
Rubi	Brazil	—	PCA	1985	High eating quality
Shinshuu	Japan	Okitsu-20 (Fukuro-gosho × Hana-gosho) × Okitsu-1 (Oku-gosho × Oku-gosho)	PCNA	1990	Medium-early ripening, high sugar content, susceptible to skin damage
Youhou	Japan	Fuyu × Jiro	PCNA	1990	Intermediate ripening, high parthenocarpic productivity
Taishuu	Japan	Fuyu × Ili G-16 (Jiro × Okitsu-15)	PCNA	1994	Big fruits, high quality
Yubeni	Japan	Matsumoto Wase-Fuyu × F2 (Jiro × Oku-gosho)	PCNA	1997	Attractive skin, late ripening
Tanrei and Kinshuu	Japan	Okitsu-2 (Fuyu × Oku-gosho) × Okitsu-15 (Oku-gosho × Hana-gosho)	PCNA	1998	Ornamental use
Soshu	Japan	Izu × 109-27 (Okitsu-2 × Okitsu-17)	PCNA	2000	Medium-large size and juicy fruits, early ripening
Kanshu	Japan	Shinshu × 18-4 (Fuyu × Okitsu-16) (Oku-gosho × Hana-gosho)	PCNA	2002	Fruit sweetness, early ripeness, no fruit cracking habits, excellent eating quality
Kishu	Japan	Izu × Akitsu-5 (Fuyu × Akitsu-16)	PCNA	2003	Big fruit, no apex cracking

non-PCNA cultivars native of Japan are homozygous dominant: natural intercrosses between PCNA and non-PCNA types were very limited in the evolution of cultivars in Japan, given the recent origin and the narrow area of diffusion of PCNA type. No F₁ PCNA offspring results in from crossing PCNAs with non-PCNAs, including “Nishimura Wase”, which had been thought to be obtained from “Fuyu” (PCNA) × “Akagaki” (non-PCNA) (Yamada and Sato, 2002). Backcrosses between PCNA × (non-PCNA × PCNA) yields around 15% and 20% of PCNA offspring (Ikeda *et al.*, 1985; Yamada and Sato, 2002).

The segregation pattern between PCNA Japanese varieties and the PCNA Chinese cultivar, “Loutian Tianshi”, resulted different, since unexpectedly non-PCNA and PCNA offsprings were obtained in a 1:1 ratio (Ikegami *et al.*, 2004). Further studies indicate that PCNA progenies are obtained also by crossing “Loutian Tianshi” with non-PCNA cultivars and that the PCNA trait of “Loutian Tianshi” is heterozygous and dominant on non-PCNA, this cultivar becoming a relevant tools for obtaining PCNA offspring (Ikegami *et al.*, 2006). Taking into account the hexaploidy of *D. kaki* and the different pathways of evolution of PCNA types

in Japan and China, confirmed also by molecular markers (Luo *et al.*, 1999; Kanzaki *et al.*, 2000), further studies on allele dosage should be carried on to clearly understand inheritance of this relevant trait.

Fruit cracking at the calyx and/or stylar ends, appearing in PCNA Japanese cultivars, and mostly when pollinated, are independent traits; they are quantitatively inherited, noncracking cultivars being homozygous and the others heterozygous (Yamada *et al.*, 1988). Hence, noncracking \times noncracking cultivars give no or little noncracking cultivars, while offsprings from highly cracking cultivars are more susceptible to these disorders: this is recurrent since quite all PCNA cultivars are cracking (Yamada *et al.*, 1988). Degree of cracking fluctuates depending strongly on the year, hence selection of noncracking genotypes is long and time spending (Yamada *et al.*, 1987c).

High sugar content (expressed as soluble solids content (SSC)) is a relevant objective in kaki breeding. Yamada *et al.* (1986, 1993, 1994a) indicated SSC trait to be quantitatively inherited and to strongly depend on environmental factors, to exhibit a low broad-sense heritability (0.47–0.69). Furthermore, estimates of variance components in the offspring populations show that choice of parent has only a small effect on the progeny for SCC (Yamada *et al.*, 1997).

Ripening time is quantitatively inherited. A study by Yamada and coworkers indicates that broad-sense heritability for this trait ranges between 0.84 and 0.92 in a population of 19 PCNA cultivars and selections (Yamada *et al.*, 1993). The coefficient of regression of mean values in a full-sib family on mid parent value was 0.99 and the values of the obtained progenies fitted with those predicted (Yamada *et al.*, 1995; Yamada and Yamane, 1997).

Fruit weight shows a high broad-sense heritability (0.85) (Yamada *et al.*, 1993). Studies carried on 39 families during 1982–1985 analyzing estimates of variance within and between progenies, showed that the expected proportion of offspring with large fruits decreased as mid-parental value decreased and inbreeding coefficient increased. It was also observed that the mean value of fruit weight of offspring in a full-sib family and the expected proportion of F_1 seedlings with higher weight could be predicted (Yamada *et al.*, 1994b; Yamada and Yamane, 1997).

Sex expression is genetically determined but pistillate cultivars can bear male flowers on rare occasions (Kajiura and Blumenfeld, 1989; Yonemori *et al.*, 2000) and sex conversion, staminate towards pistillate flowers, can be induced by applications of benzylamino purine on flower primordia (Yonemori *et al.*, 1990, 1993). Even if the presence of staminate flowers is not a breeding objective, since seedless fruits are mostly preferred, genotypes with male flowers are relevant mostly for cross-breeding. This trait seems to be quantitatively inherited: progenies obtained by crossing genotypes from high to low percentage of staminate flowers, showed a gradual reduction in the percentage of individuals with staminate flowers (Oohata *et al.*, 1964; Bellini and Giordani, 1992).

The inheritance of parthenocarpy is still unknown. Ability of parthenocarpy presents a wide variability among cultivars. Yamada *et al.* (1987b) indicated that the ability of parthenocarpic production, as percentage of fruit drop after bagging flowers to avoid pollination, fluctuates markedly, the year effect being stronger than cultivar–year interaction. On the contrary, ability of seed formation, also depending on the cultivar, shows a lower fluctuation (Yamada *et al.*, 1987b).

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

Conventional breeding of kaki has not yielded as good results as those of other fruit species, such as peach, apple, and citrus, cross-breeding program of which actively progressed worldwide. The main results achieved by cross-breeding in most of cases have no or little impact on the varietal assortment of kaki, ancestral cultivars being selected from widely cultivated native germplasm (Giordani, 2002).

In general terms, conventional breeding of kaki is hindered by the high ploidy level of *D. kaki*, which is hexaploid or nonaploid, and by its complex sex expression. Monoic cultivars are few, and most of the valuable cultivars are of pistillate type. Obstacles to achieve relevant results depend on the breeding objectives, namely when PCNA cultivars are sought.

As regards PCNA cultivars, Japanese breeding programs have had to face, for the main traits

to be improved, relevant troubles linked mainly to the narrow genetic pool of the PCNA group (Yonemori *et al.*, 2000). The main objectives were to obtain new PCNA cultivars with the following characteristics: early ripening time, large fruit size, high sugar content, high parthenocarpic productivity, limited physiological disorders (apex and styler cracking) (Yamada, 2005). Depression by inbreeding appeared on progenies showing small and susceptible to fruit cracking, and weak and low productive trees, since PCNA progenies were obtained by crossing PCNA \times PCNA, the number of PCNA parents being limited, and very few PCNA cultivars bear staminate flowers (Bellini *et al.*, 1993, 1998; Yonemori *et al.*, 2000; Yamada, 2005). On the other hand, to obtain different PCNA genotypes by crossing PCNA Japanese cultivars \times non-PCNA cultivars, the proportion of PCNA offspring resulted by back crossing F_1 (PCNA \times non-PCNA) with PCNA is very low, given the high level of ploidy of *D. kaki* and the dominance of astringency trait in Japanese native cultivars (Bellini *et al.*, 1998; Yonemori *et al.*, 2000; Giordani, 2002; Yamada, 2005). More efficient results in order to obtain PCNA progenies are expected by using "Loutian Tianshi", since the PCNA progenies are obtained in F_1 by crossing it with any astringent type (Ikegami *et al.*, 2006), although the fruit is small (69 g, against 200–250 g required by the market). The low heritability of sugar content and the yearly fluctuation of susceptibility to fruit cracking hindered cross-breeding for PCNA cultivars.

Problems also occur when the objective is obtaining new non-PCNA astringent varieties with an aim to improve those already widely used. No superior genotypes has been selected among the over 4000 seedlings obtained from different crosses and evaluated in Italy since 1970 (Bellini *et al.*, 1998; Giordani, 2002). Other critical aspects of conventional breeding are associated with the lack of known sources of resistance to the main pests and diseases affecting kaki and of other important traits for kaki industry, such as rooting ability and dwarfism.

During the past 60 years, as mentioned above, several new cultivars have been released from the kaki cross-breeding programs of the Fruit Tree Research Station in Japan (Yamada, 1993). However, rapid breeding progress through conventional cross-breeding is difficult because, as with other

woody plants, kaki has a long juvenile period and large plant size (Tao and Dandekar, 1999). Furthermore, kaki is a polyploid (Tamura *et al.*, 1998b), which makes it difficult to predict segregation of characters. Genetic transformation allows to make small specific changes in the genome of the existing excellent cultivars. Introduction of genes, which produce antibacterial substance and toxin for pests, add substance giving tolerance to environmental stresses, change metabolism of sugar and pigment of fruit, increase nutraceutical substance in fruit, prolong shelf life, improve rooting of cuttings, and make trees dwarf, into the genome of kaki would be expected. Transgenic kaki cultivars thus produced have potential for commercial success and grower acceptance because the genetic constitution of the cultivar was not altered (Dandekar, 1994). Moreover, biotechnology for kaki has intensively developed recently, including micropropagation from shoot tips (Sugiura *et al.*, 1986; Tao and Sugiura, 1992a), organogenesis from callus (Tao *et al.*, 1988; Tamura *et al.*, 1992; Tao and Sugiura, 1992b; Benelli *et al.*, 1999) and protoplasts (Tao *et al.*, 1991; Tamura *et al.*, 1995a), and somatic hybridization (Tamura *et al.*, 1995b, 1998a). Although these techniques are also powerful tools for breeding, the development of biotechnology makes it easy to create genetically modified kaki. Many countries have not approved growing genetically modified crops yet, partly because there is fear that their progeny will naturally spread through their pollens and seeds and damage the realm of nature. If the genetic transformation is applied to seedless and pistillate-type cultivars or rootstocks, the risk will be minimized.

2. DEVELOPMENT OF TRANSGENIC KAKI

2.1 Donor Gene and Transgene

Initially, in the development of genetically transformed kaki, *Agrobacterium* wild strains were used to determine which strains have virulence on kaki. Five wild-type strains of *A. tumefaciens* were used, and inoculation with three strains, A281, C58, and K12, induced tumor formation on kaki shoots *in vitro* (Tao *et al.*, 1995a). These strains successfully introduced transfer-DNA (T-DNA) of their Ti plasmid to kaki. This was evident because most calli from the tumor cell lines

Figure 3 A “Nishimura Wase” kaki shoot with crown gall tumor at the wound site where *A. rhizogenes* was inoculated (Tao *et al.*, 1994)

produced opines and showed hormone-induced autotrophic growth (Tao *et al.*, 1995a). Four wild-type strains of *A. rhizogenes* were also used for inoculation on the shoots and they successfully induced the formation of tumors (Figure 3), rather than roots (Tao *et al.*, 1994; Tamura, 1997).

The first synthetic gene integrated into the kaki genome was the *cryIA(c)* gene (Tao *et al.*, 1997). The T-DNA region of a binary plasmid vector pDU92.710 harbored in a disarmed strain of *A. tumefaciens* EHA101 contained the kanamycin resistance gene (*nptII*), the β -glucuronidase (GUS) gene, and a synthetic reconstruct of *cryIA(c)* encoding the insecticidal crystal protein fragment of *Bacillus thuringiensis* subsp. *kurstaki*.

Nakamura *et al.* (1998) used three types of binary vectors, pBI121 (Jefferson *et al.*, 1987), pTOK233 (Hiei *et al.*, 1994), and pSMAC251 (Yamashita *et al.*, 1995), to improve transformation efficiency in kaki. However, only the last one, which contained 35S promoter-*nptII* and a nopaline synthase (*nos*) promoter-*gus* and was harbored in EHA101, was successfully introduced into the kaki genome. The other vectors harbored in LBA4404 (Hoekema *et al.*, 1983) were not introduced.

The *codA* gene of *Arthrobacter globiformis*, encoding choline oxidase, was contained in the binary vector pGC95.091 (Gao *et al.*, 2000),

which was generated from pDU92.3103 (Tao *et al.*, 1995b). This vector also contains the *nptII* gene and the GUS gene (*gusA*) with the 35S promoter. Choline oxidase catalyzes the oxidation of choline to glycinebetaine (Deshrieum *et al.*, 1995), one of the water-soluble compounds of low molecular weight that are referred to as compatible solutes; it allows them to tolerate certain types of environmental stress (Hellebust, 1976). The binary vector pRS95.101, which contained only the *gusA* and *nptII* genes in the T-DNA region, was used for control transformations (Gao *et al.*, 2000).

To endow kaki with the ability to synthesize sorbitol, a sugar alcohol that may serve as an osmoprotectant in the Rosaceae, including apple, the binary plasmid vector pDU93.0305 (Tao *et al.*, 1995b) was used (Gao *et al.*, 2001). The T-DNA region of this vector contained the *nptII* gene, the *gusA* gene, and a chimeric sorbitol-6-phosphate dehydrogenase (*S6PDH*) gene that was comprised of apple complementary DNA for S6PDH and cauliflower mosaic virus regulatory sequences. Similarly, tobacco (*Nicotiana tabacum* L.), which normally does not produce sorbitol, has been engineered to produce sorbitol by expression of the transgene *S6PDH* using the 35S promoter (Tao *et al.*, 1995b).

The *rolC* gene from *A. rhizogenes* induces dwarfism (Kaneyoshi and Kobayashi, 1999). Therefore, the binary vector pSMAC251-*rolC*, which was developed from pSMAC251 (Yamashita *et al.*, 1995), containing the *rolC* and *nptII* genes was used to produce dwarfed rootstock (Koshita *et al.*, 2002). The promoters were 35S for the *rolC* gene and *nos* for the *nptII* gene.

The polygalacturonase inhibiting proteins (PGIPs) are thought to be a component of plant pathogen defense (Albersheim and Anderson, 1971). *Botrytis cinerea* lesion growth was reduced on the leaves and fruits of transgenic tomato plants expressing the pear fruit PGIP (Powell *et al.*, 2000). Both plasmid pDU94.0928, carrying chimeric genes of *PGIP* cloned from pear fruit (Stotz *et al.*, 1993), *gusA*, and *nptII*, and plasmid pYS95.091 were constructed from a base binary vector (pCGN1559; McBride and Summerfelt, 1990) for a study of the enhancement of disease resistance by transformation of kaki (Tamura *et al.*, 2004). Plasmid pYS95.091 had the same construction as pDU94.0928, but without the chimeric *PGIP* gene.

2.2 Transformation Methods

All transformation experiments of kaki have been carried out using *Agrobacterium* because the system is well developed. The first synthetic gene transfer into the kaki genome was conducted using EHA101 (Hood *et al.*, 1986) because the wild type strain of EHA101, A282, is very virulent on kaki (Tao *et al.*, 1995a). Nakamura *et al.* (1998) found that EHA101 was a more suitable strain for transformation than LBA4044. Hence, EHA101 has been used in most kaki transformation works using *Agrobacterium*.

Leaf discs were used as one of the plant materials (Tao *et al.*, 1997; Gao *et al.*, 2000, 2001; Tamura *et al.*, 2004). Leaf discs of 8 mm in diameter were collected from *in vitro* leaves, precultured on MS (1/2N) medium containing zeatin and α -naphthalene acetic acid for 3 days at 28 °C in darkness, inoculated by immersion for 15 min in low-pH (5.2) virulence-induction medium (James *et al.*, 1993), and then cultivated with *Agrobacterium* for 3 days at 28 °C in darkness. After co-cultivation, the leaf discs were transferred to fresh aliquots of the same medium with an antibiotic to kill the bacterial cells. After 3 days, leaf discs were transferred to a selection medium with kanamycin. Spent medium was replaced by fresh medium every 2 weeks. During selection, calli that had formed at the cut surface of the leaf discs were collected to induce the formation of transformed shoots (Figure 4). The frequency of callus formation varied by study: 2% (Tao *et al.*, 1997), 12–14% (Tamura *et al.*, 2004), and

>20% (Gao *et al.*, 2000). Tamura *et al.* (2004) conducted fluorometric GUS assays on calli to select those that were transformed. They found that the transformation rates with the *gusA* gene of pDU94.0928 and pYS95.091 were 9.1% and 7.7%, respectively.

Hypocotyl segments prepared from embryos in seeds were used as the other plant material (Nakamura *et al.*, 1998; Koshita *et al.*, 2002). The hypocotyl segments were immersed in the bacterial suspension for 15 min, and thereafter placed on co-culture medium consisting of MS (1/2N) medium containing acetosyringone and zeatin. After co-cultivation for 3 days at 28 °C in darkness, segments were transferred to a selection medium with kanamycin. The cultures were maintained at about 26 °C under a 16 h photoperiod and were subcultured every month to induce the formation of adventitious shoots at the cut end of each segment.

Addition of acetosyringone to the co-culture medium was used to increase the virulence of *Agrobacterium* (Nakamura *et al.*, 1998). Cefotaxime effectively removed *Agrobacterium* after inoculation (Tao *et al.*, 1997; Nakamura *et al.*, 1998), but carbenicillin sulfate inhibited bud formation on hypocotyl segments (Nakamura *et al.*, 1998).

To our knowledge, except gene gun (Benelli *et al.*, 1999), there have been no reports of successful transformation of kaki by other methods including electroporation, microinjection, or polyethylene glycol. These methods are worth investigating because plant regeneration systems

Figure 4 Regeneration of transformed kaki cv. Jiro. (a) a putative transformed callus formed on the inoculated leaf disc cultured with kanamycin; (b) adventitious bud formation from the transformed callus (Tao *et al.*, 1997)

from shoot tips (Sugiura *et al.*, 1986; Tao and Sugiura, 1992a), leaves (Tao *et al.*, 1988), roots (Tetsumura and Yukinaga, 1996), calli (Tao *et al.*, 1988; Tao and Sugiura, 1992b; Tamura *et al.*, 1992; Benelli, *et al.*, 1999), hypocotyls (Yamada *et al.*, 1987a), and protoplasts (Tao *et al.*, 1991; Tamura *et al.*, 1995a) of kaki are well developed.

2.3 Selection of Transformed Tissue

Kanamycin has been used exclusively for the selection of transformed tissue in kaki because plasmid T-DNA regions used in all transformations of kaki have contained the *nptII* gene. All of the control untransformed calli cultured on medium without kanamycin formed adventitious buds, whereas only 20% of the control calli formed buds on medium with kanamycin, and no further growth of the adventitious buds induced from the control calli was observed on shoots in medium with kanamycin (Tao *et al.*, 1997). Although it is possible that other antibiotic-resistant and herbicide-resistant genes will be used as selection makers, kanamycin is a good tool for the selection of transformed tissue, and its application has been improved (Nakamura *et al.*, 1998).

An assay for GUS activity was also conducted to confirm putative transformed lines in all studies. Leaves and leaf discs from the shoots were used in GUS assays and they performed well (Tao *et al.*, 1997; Nakamura *et al.*, 1998). Callus was also used for GUS assays in some cases (Gao *et al.*, 2000; Tamura *et al.*, 2004).

2.4 Regeneration of Whole Plant

Of the 17 kanamycin-resistant calli formed on leaf discs ($n = 720$) after infection by *Agrobacterium*, 15 formed adventitious buds on the regeneration medium (Tao *et al.*, 1997). The frequency reported by Gao *et al.* (2000) was also high (90–100%). These frequencies were comparable to those of the untransformed calli of the same cultivar, “Jiro” (Tamura *et al.*, 1992). However, the regeneration rates were considerably lower for transformed lines than for untransformed calli when the *PGIP* gene was introduced; furthermore, the control transformed line without the *PGIP* gene showed a comparably low regeneration rate compared to the line with the gene (Tamura *et al.*, 2004).

The frequency of bud formation on hypocotyl segments after infection by *Agrobacterium* was 14.9–27.0%. However, the shoots regenerated from the segments directly, not through callus, so transformants were obtained within a relatively short time (Nakamura *et al.*, 1998).

The frequency of transformed GUS(+) shoot formation differentiated from the callus formed on leaf discs was 1.3% (Tao *et al.*, 1997), whereas that from the hypocotyl segments was 11.1% (Nakamura *et al.*, 1998). Clearly, the regeneration ability of the plant material was responsible for the difference in frequency (Nakamura *et al.*, 1998). However, Gao *et al.* (2000) increased the frequency of transformed GUS(+) shoot formation from the callus on leaf discs by modifying the concentration of zeatin during the initial period of transformation. Under those conditions, 18% and 10% of the leaf discs produced transformed shoots by pGC95.091 and pRS95.101, respectively.

A method for the rooting of microcuttings has been established (Tao and Sugiura, 1992a), allowing the development of whole plantlets. When necessary for further investigation, plantlets were obtained from transformed shoots, except for “Fuyu” shoots with introduced Ri T-DNA (Tao *et al.*, 1994) and one “Jiro” shoot line with the *PGIP* gene (Tamura *et al.*, 2004). The rooting ability of transformed shoots varied with the gene introduced; for example, rooting was high in *rolC* (Koshita *et al.*, 2002) and low in Ri T-DNA (Tao *et al.*, 1994) and *PGIP* (Tamura *et al.*, 2004). Because transformed lines, including a control transformed line, had lower rooting rates, Tamura *et al.* (2004) suggested that rooting is affected by the overall transformation process, as well as the regeneration rate from callus.

2.5 Activity and Stability of Gene Inheritance, and Adverse Growth Effects

Tao *et al.* (1997) used kaki plants integrated with synthetic *cryIA(c)*, which produces a 60-kDa insecticidal crystal protein fragment (ICPF; Adang *et al.*, 1985) for screening of insect resistance using the Indian meal moth (IMM), *Plodia interpunctella*. This moth is a pest of stored products worldwide, and it is quite susceptible to ICPF (Vail *et al.*, 1991). The lines producing

Figure 5 Appearance of the leaves from the transformed kaki with the *cyrIA(c)* gene of *Bacillus thuringiensis* and the control nontransformed plants after 7 days of feeding with oriental moth larvae (Tao *et al.*, 2001)

CryIA(c) protein showed highly significant mortality of IMM when compared to untransformed controls and one transformed line, which did not produce detectable CryIA(c) protein. Using the two transformed lines that showed the highest mortality, they further evaluated insect resistance because IMM is not a pest of kaki. A natural insect pest of kaki, the oriental moth (OM) larvae, *Monema flavescentis*, was used for bioassays, and the lines producing CryIA(c) protein caused significantly higher mortality of OM larvae than those that did not produce the protein (Figure 5). The field test trees were grown at the University of California at Davis (Figure 6).

Of the eight transformed lines producing choline oxidase by the *codA* gene, two lines (PCs) producing high levels of glycinebetaine (0.16

Figure 6 The transformed kaki trees growing at the University of California at Davis

and $0.28 \mu\text{M g}^{-1}$ fresh weight) and the control transformed line (PR) lacking glycinebetaine (Gao *et al.*, 2000) were selected for evaluation of tolerance to salt stress. Transgenic plants showed normal growth, resembling wild type plants both *in vitro* and *ex vitro*. Although the activity of photosystem II in the PCs and PR declined under salt stress, the rate of decline was lower in the PCs than in the PR. This result demonstrated that genetic engineering of kaki for the accumulation of glycinebetaine enhanced its tolerance to salt stress. This has also been accomplished in *Arabidopsis* (Hayashi *et al.*, 1997; Alia *et al.*, 1998) and rice (Sakamoto *et al.*, 1998).

Other salt-tolerant transformants producing sorbitol by the chimeric S6PDH gene were used in the evaluation, including two transformed lines producing high (PS1) and medium (PS6) amounts of sorbitol, one control transformed line (PS7) with no ability to synthesize sorbitol, and an untransformed type ("Jiro"; Gao *et al.*, 2001). As a result of the same salt stress evaluation system tested, PS1 appeared to be more tolerant to salt stress than the other three lines. Moreover, PS1 had reduced stature with shorter internodes and more lateral growth with more branching compared to the other lines, although it grew normally *in vitro* and during the early stage of *ex vitro* growth. Enhanced tolerance to salts and slower growth in transgenic tobacco plants with the ability to produce mannitol, another compatible solute, has also been observed (Karakas *et al.*, 1997). Hence, further investigation of induced dwarfism (Deguchi *et al.*, 2004) in these lines was conducted. Given the fact that glucose 6-phosphate, indole-3-acetic acid, and gibberellin levels did not affect dwarfism in PS1 in comparison with PS7, the control, and the wild type, Deguchi *et al.* (2004) deduced that growth inhibition of PS1 was likely caused by an osmotic imbalance between the cytosol and vacuole owing to high sorbitol accumulation in the plants.

Heights and internode lengths of the transformed kaki with *rolC* were shorter than those of the untransformed plants, and the leaves of transformants were smaller (Koshita *et al.*, 2002), which has also been observed in pear (Bell *et al.*, 1999). Furthermore, a higher rooting rate of *in vitro* shoots was also observed, and this ability, along with dwarfism, is a horticulturally preferred characteristic. Dwarfism should be confirmed by

investigation of the growth of scions grafted on the transformants (Koshita *et al.*, 2002).

Following Taylor and Secor (1988), PGIP activity in shoots transformed with EHA101/pDU94.0928 and EHA101/pYS95.091 was analyzed using a radial diffusion assay (Tamura *et al.*, 2004). Fungal polygalacturonase (PG) activity was inhibited by crude extracts from shoots transformed with the *PGIP* gene. The inhibition was substantially stronger than that in the control transformants obtained from the transformation with pYS95.091 and in the untransformed plants. The fact that the controls showed mild inhibition of PG support the idea that kaki leaf tissue expresses an endogenous PGIP-encoding gene that is relatively dissimilar to the pear *PGIP* transgene because it was not detected in the DNA and protein blotting analysis (Tamura *et al.*, 2004).

All of the studies discussed here considered only the growth and reaction of the plants, not the fruit. It is necessary to investigate the quality of fruit harvested from transformants. For further studies, transformed plants should be planted in a field and allowed to bear fruit. Also, the heredity of the transgene in kaki is an interesting subject of inquiry.

2.6 Regulatory Measures

Field tests of the transformed kaki are now performed only in California (Figure 6). There is no cultivation of transformed plants in Japan, where most research on transformation of kaki has been conducted, partly because there are strict regulations for field tests of transformed crops and public acceptance of GMO foods has not increased. Recently, field tests on the transformed fruit trees were initiated in Japan (Tao *et al.*, 2001). Regulations for cultivating the transformed fruit trees in Japan may be established during the study.

3. FUTURE ROAD MAP

3.1 Expected Products

Previous works have shown how engineering tolerance to salt stress, growth inhibition, and resistance to pests and disease has developed. These genetic improvements are all related to

the culture of kaki, but kaki fruit is so rich in vitamin C, carotenoids, pectic substances, and polyphenols that there may be little interest in improving its nutraceutical quality by introducing foreign genes into the kaki genome.

As mentioned before, the main breeding objective for kaki is to obtain PCNA cultivars with many valuable characteristics, but Japanese breeding programs have had difficulties linked mainly to the narrow genetic pool of the PCNA group (Yonemori *et al.*, 2000). However, if non-PCNA cultivars producing fruit of high quality are transformed into PCNA, the breeding program will be changed dramatically. For example, seedless PCNA cultivars will appear relatively soon by transforming an excellent non-PCNA cultivar ("Hiratanenashi"), although nonaploid PCNA types may result from cross-breeding (Sugiura *et al.*, 2000; Yamada and Tao, 2006).

3.2 Addressing Risks and Concerns

Kaki originated in China and is naturally distributed in East Asia. Hence, the assessment of risk to the environment should begin in East Asia. As for damage to human health, assessment of fruit harvested from trees on transformed rootstocks, as well as fruit harvested from transformed scion cultivars is needed. These assessments, conducted within a country following a set of national guidelines, will enhance the possibility of the cultivation of transformed kaki worldwide.

3.3 Expected Technologies

The efficiency of kaki transformation using *Agrobacterium* is not lower than that of other fruit trees and is higher than that of apple (Kotoda *et al.*, 2006) and grape (Nakajima *et al.*, 2006). However, using another marker such as green fluorescent protein (Yancheva *et al.*, 2006) or using positive selection (e.g., mannose; Ramesh *et al.*, 2006) might improve efficiency.

For the leaf disc transformation system developed by Tao *et al.* (1997), a callus intermediate stage was indispensable to obtain transformants. Earlier work had shown that it is difficult to induce adventitious bud formation directly from leaf discs (Tao *et al.*, 1988). The major drawback in using a callus intermediate stage is

that the regeneration process takes longer and there is a risk of somaclonal variation (Tao and Dandekar, 1999). In contrast, for the hypocotyl segment transformation system developed by Nakamura *et al.* (1998), transformed shoots were regenerated directly from the segments, so that transformants were obtained rapidly. However, this transformation method cannot be used to introduce genes into cultivars directly because it uses hypocotyls that are of cross-bred origin. Hence, *in vitro* root segments of cultivars are promising materials for transformation using *Agrobacterium* because the technique for the induction of adventitious shoots directly on a root segment has been established (Tetsumura and Yukinaga, 1996). However, no adventitious buds formed on “Saijo” roots co-cultivated with *Agrobacterium* EHA105 (Itamura *et al.*, 2006).

All of the promoters used in the transformation of kaki have been 35S, except for the *nos* promoter with the *nptII* gene in pSMK251 (Nakamura *et al.*, 1998; Koshita *et al.*, 2002). Recently, gene expression of kaki has been investigated intensively for ethylene production (Nakano *et al.*, 2003; Zheng *et al.*, 2005, 2006; Ortiz *et al.*, 2006) and tannin biosynthesis (Ikegami *et al.*, 2005a, b) of fruits. These studies might lead to the detection of a promoter specific to the maturation of kaki fruit. A fruit-specific promoter for other species (Yamagata *et al.*, 2002) may be used as an alternative promoter for introducing genes into the kaki genome.

A future improvement in the transformation system of kaki involves the establishment of many valuable cultivars (Tao *et al.*, 2001), although “Jiro,” the only transformed cultivar, is an important PCNA cultivar. The key to success may lie in enhancing adventitious bud formation from callus cultures because more than half of the cultivars tested did not form adventitious buds (Tao and Sugiura, 1992b). Transformants from kaki seedlings can be used as rootstocks (Koshita *et al.*, 2002) and as research models for the juvenile phase (Kotoda *et al.*, 2006).

3.4 Future Release and its Consequences

Although all studies discussed here were experimental, all genes used for the transformation of kaki were eminently practical. Hence, a new

cultivar integrated with the genes considered here might be released after field testing. There are many issues concerning intellectual property, public perceptions, political consequences, and economic consequences that must be discussed and solved.

1. INTRODUCTION

Tomato is one of the most consumed and widely grown vegetable crops in the world. Wild-type tomato species are thought to be native of western South America, specifically in the dry coastal desert of Peru. Tomato crop is valued at 5–6 billion dollars, with international trade amounting to 3–3.5 billion dollars annually (FAOSTAT, 2005). Tomato is grown on about 4.5 million hectares with a production of 122.6 million metric tons worldwide. In 2005, Asia was the highest tomato-producing continent with over 49% (or 60 243 562 t) of the total production. Americas ranked second in the world with a production of ~20 million metric tons, with North America producing the major quantity. Based on the average world production from 1999 to 2005, the top 10 tomato-producing countries are: China, the United States, Turkey, India, Italy, Egypt, Spain, Iran, Brazil, and Mexico. China contributed over 25% (or 31.6 million metric tons) to the total world production during the year 2005 (FAOSTAT, 2006).

In the global export market of tomatoes, Spain has been the world's leading exporter, with \$972 million export in 2004, Mexico being close second with \$909 million, followed by Canada. The United States ranks fourth in export value with \$233.8 million in 2004 (FAOSTAT, 2006). The

North American Free Trade Agreement (NAFTA) between United States, Canada, and Mexico resulted in higher export quantity of 1 244 568 t with an export value of \$1415 million in 2004 (FAOSTAT, 2006). Canada and Mexico are the largest export destinations for US fresh tomatoes with over 80% of US fresh tomato at a value of \$141.7 million exported to Canada alone in 2004. The summer and fall are the prime seasons for tomato export from the United States to Mexico but the value of shipments to Mexico is variable (Boriss and Brunke, 2005). In spite of the fact that the United States has higher tomato production, it was the leading importer of fresh tomatoes in 2004 (FAOSTAT, 2006).

The tomato was not very popular until the 18th century mainly because it was rumored to be poisonous. The first improved cultivated tomatoes were Tilden, released in 1865, and Trophy, released in 1870 (Bailey, 1949; Robertson and Labate, 2007). Thomas Jefferson grew tomatoes in Virginia. George Washington Carver encouraged introduction of tomatoes in the diet and was known to eat tomatoes in front of crowds. The popularity of the tomato comes not only from its flavor and freshness (fresh market tomato), but also because it can be processed as: ketchup, sun dried, tinned, powder, sauce, soup, puree, juice, canned whole fruit, etc. (processing tomato industry). Tomato processing began in 1847, when

Harrison Woodhull Crosby, the chief gardener at Lafayette College, developed a crude method of canning tomatoes (Boriss and Brunke, 2005). Tomato processing has come a long way since the use of jars in home preserve (Salunkhe and Desai, 1984). Prior to 1890, all tomato canning was done by hand. Industry techniques improved with canning technology, and tomato juice came on the market with the development of the juice extractor in the 1920s (Gould, 1983). Processed tomatoes account for the majority of tomato tonnage in the United States, while the comparatively higher prices of fresh market tomatoes make them higher ranked in terms of value. Today, the United States produces over 10 million tons of processing tomatoes, in which California processes over 90% of the total.

Tomato is a very versatile vegetable for culinary purposes. Unripe green tomatoes are used to make preserves, salsa, be breaded and fried, or be pickled. Tomatoes are used extensively in the Mediterranean and Middle Eastern cuisines, especially Italian. Tomato fruit is acidic, a property that is used to bring out other flavors. This same acidity makes tomatoes especially easy to preserve in home canning as tomato sauce or paste. Such versatility coupled with a growing demand for the fresh fruits, has pushed the development of tomato as a one of the main crops of the last century and the beginning of this new millennium.

Tomato is a popular vegetable/fruit also because it is an important source of vitamins and minerals in diets. One medium-sized tomato provides 57% of the recommended daily allowance (RDA) of vitamin C, 25% RDA of vitamin A, and 8% RDA of iron, yet with only 35 calories. Tomato extract has been used to treat various diseases in traditional medicine in different countries such as Japan, Greece, Peru, and Guatemala. Hot water extract of dried fruits has been used in the treatment of ulcers, wounds, hemorrhoids, and burns (Caceres *et al.*, 1987). Tomatoes are also rich in an antioxidant called lycopene, a carotenoid that has been found to protect cells from oxidants that have been linked to cancer (Gerster, 1997). In laboratory tests, lycopene was found to be twice as powerful as β -carotene in neutralizing free radicals. Lycopene has been linked to risk reduction in a number of cancer types, including prostate, lung and stomach, pancreatic, cervical, colorectal, oral, and

esophageal cancers (Giovannucci, 1999; Rao and Agarwal, 2000). Giovannucci *et al.* (1995) reported that the risk of prostate cancer was reduced nearly 45% among men who ate at least 10 servings a week of tomato-based foods. Compared with carotenoids and other antioxidant compounds including vitamin E, lycopene has been reported to be a more efficient quencher of singlet oxygen *in vitro*. In addition to its antioxidant and anticarcinogenic properties, lycopene shows an array of biological effects including cardioprotective, anti-inflammatory, and antimutagenic activities. The mechanisms underlying the inhibitory effects of lycopene on carcinogenesis could involve reactive oxygen species scavenging, upregulation of detoxification systems, interference with cell proliferation, induction of gap-junctional communication, inhibition of cell cycle progression, and modulation of signal transduction pathways (Bhuvaneswari and Nagini, 2005).

1.1 Botanical Description

Tomato is a member of the dicot family Solanaceae, which contains well-known plant species such as potato, tobacco, eggplant, and pepper. Bailey (1949) classified tomatoes as belonging to two species: *Lycopersicon pimpinellifolium* and *Lycopersicon esculentum*. The latter species is the parent of commercial tomatoes, and practically all belong to the botanical variety *Commune*. Other botanical varieties included in this species are: *Grandifolium*, the large-leaved or potato-leaved type; *Validum*, the upright or dwarf type, with dense, dark green foliage; *Cerasiforme*, the cherrylike type, with normally two-celled globular fruits and standard foliage; and *Pyriforme*, the pearlike type or oblong fruits and standard foliage. In addition to these two species, several more species of tomato are recognized, namely, *Lycopersicon cheesemanii*, *Lycopersicon peruvianum*, *Lycopersicon hirsutum*, and *Lycopersicon glandulosum* (Taylor, 1986). The current range of wild tomato relatives extends from the northern tip of Chile on the south, to Ecuador on the north, and reaching inland from the Pacific 100–200 miles (161–322 km), also including the Galapagos Islands (Gould, 1991).

Miller's classification (Miller, 1754) of tomato under the genus *Lycopersicon* continued to be

used until now. However, the recent molecular studies on phylogenetic relationships within the family of Solanaceae support and firmly re-establish Linnaeus' (1753) earlier classification of tomato under the genus *Solanum* (Peralta and Spooner, 2007; see other chapters in Razdan and Mattoo, 2007). Linnaeus had grouped all the cultivated multilocular tomato species under the name of *Solanum lycopersicum*. Whereas the location of domestication is not well established, the most acceptable explanation is that tomato dispersed to Mexico (and much of the rest of Latin America) as a weedy form and subsequently was domesticated there (Jenkins, 1948). Therefore, our modern tomato cultivars, while not necessarily arising directly in the center of origin, have their root beginnings on the west coast of Latin America (Mills, 2006).

The genus consists of a warm-season perennial plant cultivated as an annual and it is very sensitive to chilling and freezing temperatures. Tomato fruit take about 6–7 weeks from flowering, depending on temperature, to reach full size. Cell division continues for about 2 weeks after flowering, but the bulk of the increase in fruit size is the result of cell expansion (Srivastava and Handa, 2005; Handa *et al.*, 2007). In normal cultivars, the first appearance of red or pink color at the blossom end signals the completion of growth and onset of ripening. Laboratory studies with fruit harvested at mature green stage have shown that ripening actually begins about 2 days before the external color changes (Madhavi and Salunkhe, 1998).

Tomato plants are described as determinate, semi-determinate, or indeterminate. The term “determinate” refers to the plant growth habit. Determinate tomato plants grow outdoors like a bush to a certain size (about 3–5 ft.), set fruit, and then decline. Most of the early ripening tomato varieties are of the determinate type. The primary shoot terminates in a flower cluster, forcing side shoots to develop. The branches terminate their growth at approximately the same distance from the crown, resulting in a compact and symmetrically circular growth. With the indeterminate types, the primary shoot dominates the side shoot development, resulting in a sprawling growth pattern. The primary shoot continues to grow as long as the plants remain healthy and growing conditions are suitable or until frost or disease kills them. Many of the

standard-sized, all-summer tomatoes typical of the home garden are of the indeterminate type. They require physical support of some kind for best results, since the fruit would otherwise be in contact with the soil and thus susceptible to rot. The semi-determinate types have vine characteristics that are intermediate between the other two types (Madhavi and Salunkhe, 1998).

The fruit is an edible, brightly colored (usually red, from accumulation of the pigment lycopene) berry, 1–2 cm diameter in wild plants, commonly much larger in cultivated forms. The fruits vary in shape from a flat round to a true round, square round, oblong, pear, oxheart, and many variations in between. The fruit is a fleshy berry, or, in botanical terms, a swollen ovule. The body of the fruit, developed from the ovary wall that surrounds and encloses the seed, which is known as the pericarp (Gillaspy *et al.*, 1993). The pericarp of tomato fruit is composed of three distinct tissue types: the endocarp, a unicellular layer encasing the locular cavity, the mesocarp, a multicellular layer of large, thin-walled parenchyma cells (>500 μ m diameter) and vascular tissue, and the exocarp (fruit skin), which is composed of an outer epidermis with a thick waxy cuticle (Osman *et al.*, 1999) and two to three layers of thick-walled hypodermal cells (Ho and Hewitt, 1986). The locular cavities occur as gaps in the pericarp and contain the seeds embedded in a jellylike parenchymatous tissue originating from the placenta. The number of locules in normal fruit varies from two upwards, and is more or less characteristic for each variety. Prior to pollination, as well as during a relatively short period after anthesis, the growth of the fruit is mainly by cell division, after which cell enlargement is responsible for the growth of the fruit. During the later phase, vacuoles appear in the cells and differentiation in composition becomes evident. Growth-promoting and growth-inhibiting substances moving into and out of the fruit no doubt play a major part in the maturation process, while respiratory and fermentative mechanisms assume a dominant role in ripening (Hobson and Davies, 1971). The color of mature fruits may be red, pink, orange, yellow, or white. Most commercial cultivars are red or pink.

Tomato fruit is classified as a climacteric fruit, in which onset of ripening is accompanied by an increase in both respiration and ethylene

production. Ethylene plays a central role in both the initiation of early biochemical events during ripening and the integration of subsequent changes (Mattoo and Suttle, 1991). The disappearance of starch, degradation of chlorophyll, and synthesis of carotenoids such as lycopene, flavor components, as well as a considerable increase in polygalacturonase and other cell wall-hydrolyzing enzymes, are processes highly integrated with the increases in respiration and ethylene production (Giovannoni, 2004; Mattoo and Handa, 2004; Srivastava and Handa, 2005). The terminal period of maturation occurs before or after harvest with little loss in edible quality provided that the mature green stage (preclimacteric minimum respiration rate) is reached before harvesting. The physiological and biochemical changes associated with ripening have been previously reviewed (Salunkhe and Desai, 1984; Hobson and Grierson, 1993; Giovannoni, 2004; Razdan and Mattoo, 2007).

1.2 Genome Size

Solanaceae members have differences in genome sizes. However, most, if not all, share the same basic chromosome number of 12 with tomato having the smallest haploid genome size of 953 Mb (Arumuganathan and Earle, 1991). Comparative genetic studies revealed that tomato and potato share very conserved colinearity between their genomes (Bonierbale *et al.*, 1988; Tanksley *et al.*, 1992). Tomato shares conserved gene repertoires with pepper even though their gene order is different (Tanksley *et al.*, 1988). Among geneticists, tomato is considered an ideal model crop plant. Tomato has an excellent classical morphological map, a high-density molecular map containing more than 1000 markers (Rick and Yoder, 1988; Tanksley *et al.*, 1992; Broun and Tanksley, 1996), and a large collection of well-characterized mutants and near-isogenic lines (NILs). In addition, tomato has a relatively small genome size, several large-insert yeast artificial chromosome (YAC) libraries (Martin *et al.*, 1992; Bonnema *et al.*, 1996), a transposon tagging system (Briza *et al.*, 1995), and a routine *Agrobacterium*-mediated transformation system (McCornick *et al.*, 1986).

1.3 Traditional Breeding

Tomatoes to be used either fresh or in processing must have distinct quality characteristics. Fresh tomatoes must have acceptable flavor, color, texture, and taste parameters to satisfy consumer demands and handling requirements. Processing tomatoes, on the other hand, must have intrinsic rheological characteristics that make them suitable for various processing applications, such as juice, ketchup, or sauce production.

The general pattern of the breeding program appropriate to a particular species is determined in part by the reproductive or mating system of the species. Tomato is a self-pollinated species. All varieties are highly inbred populations with no significant genetic diversity within a variety. It has generally been found that self-pollinating plants such as tomatoes, after they have become stabilized, do not change their genetic constitution to any great extent (Kerr, 1969).

Tomato has perfect flowers. Crossing of tomatoes is accomplished by emasculation of the flowers of the seed parent as they begin to open but before pollen is shed. In order to emasculate a flower, the stamens are removed with forceps, either alone or with the petals. Pollen is collected on the tip of a sterile forcep from the pollen parent and placed on the stigma of flowers of the seed parent. When the fruit is ripe, the seeds are extracted, fermented naturally or digested with acid, washed, dried, and packaged. Selfing plants of this first generation cross (F_1) yields the F_2 generation, or crossing F_1 to one of the parents (backcrossing) gives the backcross (BC) generation (George and Berry, 1983).

The basic breeding used following hybridization includes pedigree and BC methods. These methods are used to handle the segregation populations and are based on the fact that selfing or backcrossing to a homozygous parent leads to homozygosity upon self-fertilization. Continued self-pollination causes an increase in homozygosity by one-half per generation. The pedigree method is widely used by tomato breeders. In this system, records are kept of the ancestry or pedigree of each of the progenies (families). Selection is based on productivity and other horticultural characteristics of single plants or progenies. After the F_2 generation, selection is practiced within and between families. Considerable detailed record keeping is required,

and the number of selections under test can quickly become burdensome. Once a degree of uniformity is reached, selections are placed in comprehensive evaluation trials (George and Berry, 1983).

The BC methods are particularly useful in transferring specific genes into an established variety deficient in one or a few characteristics. It is very effective in transferring genes for disease resistance. Continued backcrosses are made to the desirable parent, and selection is practiced for the characters being transferred from the donor parent. Essentially, the new variety will be the same as the original parent except for its improved characteristics. This is an advantage because of the fact that the new variety need not be extensively evaluated. It has the disadvantage in that the new variety will only have the specific improvements transferred. Many programs utilize a combination of the pedigree and BC methods. The BC system is used early in the program to transfer specific genes, but while sufficient heterozygosity exists pedigree selection is undertaken to improve other horticultural characters (George and Berry, 1983).

Traditional breeding requires the selection of a tomato genotype or its wild species that has a desirable trait, such as early ripening, disease resistance, and crossing it with another tomato cultivar that has a good genetic background. The desired result is an earlier ripening tomato that makes it to the market sooner, or varieties that resist the pathogens' attack. In this way, several thousands of tomato cultivars were developed. In the United States, as an example, developed cultivars include: Better Boy F₁, Burpee's Big Boy F₁, Campell 1327, Dombito F₁, Earlypak 707, Glamour, Heinz 722, Heinz 1350, 1439, 2653, Jubilee, Jumbo F₁, New Yorker, Red Cherry, Roma VF, Rutgers 39, Spring Set F₁, Supersonic F₁, Traveler 76, UC 82, UC 204, among others (Madhavi and Salunkhe, 1998).

Since the early days of the 20th century, traditional breeding for disease resistance in plants has been a major method for controlling plant diseases. Varieties that are resistant or tolerant to one or few specific pathogens are already available for many crops. Resistant hybrids with multiple resistances to several pathogens exist and are currently used in vegetable production. For tomato, the genetic control of pathogens is a very useful practice and most of used resistance is monogenic and dominant. So far,

tomato breeding has resulted in varieties with resistance to at least 15 pathogens, although with varying stability and level of expression (Grube *et al.*, 2000). Tomato varieties with some resistance to fungi or oomycetes (*Alternaria alternata* f. sp. *lycopersici*, *Cladosporium fulvum*, *Fusarium oxysporum* f. sp. *lycopersici*, *Fusarium oxysporum* f. sp. *radicis-lycopersici*, *Phytophthora infestans*, *Pyrenochaeta lycopersici*, *Verticillium dahliae*), bacteria (*Corynebacterium michiganense*, *Pseudomonas solanacearum*, *Pseudomonas syringae* pv. *tomato*), virus (beet curly top hybrigeminivirus, tomato mottle bigeminivirus, tomato spotted wilt tospovirus, and several variants of the tomato yellow leaf curl bigeminivirus), and nematodes (*Meloidogyne* spp.) are available (Lacerrot, 1996). Many open-pollinated varieties presently cultivated possess genetic resistance to three or four pathogens. With the increasing use of F₁ hybrids it is possible to use varieties combining from four up to six resistances (Grube *et al.*, 2000).

In processing tomatoes, the major breakthrough had been the advent of the once-over machine for harvesting in the late 1960s. The breeding and development of tomato varieties for machine harvest adapted to any region is complex. For once-over machine harvest, concentrated fruit setting and maturity are important considerations; however, there are many sources of plant material that can produce variations in plant growth habit, concentrated flowering, fruit setting ability, concentrated maturity, and ability of the ripe fruit to store on the vine, than presently available in commercial varieties (see Razdan and Mattoo, 2007). In general, the materials that have variations in concentrated plant habit and higher degree of earliness have been of limited use due to low yield potential and deficiencies in quality, such as small fruit size, lack of firmness, crack susceptibility, low solids, and poor color (Gould, 1991).

1.4 Rationale for Transgenic Technology Application

Conventional plant breeding has had a significant impact on improving tomato breeding for fruit quality and resistance to important diseases. However, the progress made thus far has been confounded by: the time-consuming process of making crosses and backcrosses; difficulty in

combating the evolution of new virulent pathogens or breakdown of resistance; saturation of the genetic pools available for improvement; and time required, 10–15 years, to release a new tomato variety. Besides, traditional breeding methods used may not impart the desired characteristics (Gould, 1983).

Genetic engineering or “recombinant-DNA technology” is a radical new avenue for transplanting genetic characteristics of one species into another. This technology is based on identifying the molecular unit(s) responsible for the desired agronomic trait and then isolating and determining the structure and organization of such a unit or units. The unit(s) can then be engineered to transform and modify any existing variety of a crop plant. This technology provides a continuum between plant breeding-based varietal development and manipulation of beneficial genes by genetic engineering to develop transgenics. Moreover, the cloned gene can be introduced not only into the plant species from which it was isolated, but also to other agriculturally important species (Peleman and Rouppe van der Voort, 2003). Using this approach, the time needed to release a new tomato variety can be halved as compared with the time taken using traditional breeding methods.

In order to establish a successful program of practical plant genetic engineering, it is important to develop a system for the recovery of large number of whole plants from explant tissues. It is also important to optimize the procedure for inserting foreign or modified host genes into the targeted plant genomes. A combination of these two approaches is required for plant genetic engineering. Early experiments involving gene transfer used *Agrobacterium tumefaciens* for introducing foreign genes (Barton and Brill, 1983; Herrera-Estrella *et al.*, 1983). *Agrobacterium* is a very effective tool for introduction of transformed genes into solanaceous species. The limitation of host specificity that made it difficult to transform crops like legumes and cereals has been partially tackled. The reproducibility of this approach has made it a method of choice for solanaceous species. On the other hand the biolistic method has emerged as a simple and promising alternative for transformation. Particle bombardment offers opportunities for successful transformation of many plant tissues without

limitation. Particle bombardment is a technique through which metal particles coated with DNA are rapidly accelerated into plant tissues, often resulting in stable transformation (Christou *et al.*, 1988; Fromm *et al.*, 1990; Gordon-Kamm *et al.*, 1990; Bower and Birch, 1992; Vasil *et al.*, 1992). Because DNA is being shot into cells, it represents a type of biological ballistics (Sanford, 1990).

Using tools derived from the recombinant-DNA technology, several genes involved in disease resistance in tomato plants and fruit development and ripening have been cloned and characterized for the creation of new transgenic tomatoes. So far, over 40 genes (including many single genes and quantitative trait loci, QTL) that confer resistance to major classes of plant pathogens have been mapped on the tomato molecular map and/or cloned from solanaceous species. The map provides a basis for further identification and mapping of genes and QTLs for disease resistance and other attributes, and should be useful for marker-assisted selection (Grube *et al.*, 2000).

Also, several genes involved in fruit development and tomato ripening have been identified, cloned, and characterized for the creation of genetically modified new tomato varieties. Of the various genes identified, those encoding the enzymes polygalacturonase (PG) and pectinesterase were utilized for targeted single-gene modification studies. Genetically modified tomatoes with reduced levels of these cell wall modifying enzymes have been successfully developed (Tieman *et al.*, 1992; Schuch, 1994). Based on these studies, an improved quality low-PG fresh market tomato named Flavr SavrTM was developed. This tomato contains an antisense version of the PG gene as well as a bacterial marker gene that confers resistance to the antibiotic kanamycin. The presence of this gene attracted opposition to Flavr Savr from critics of genetic engineering and consumer-activist groups, who claimed that the gene might jeopardize the use of kanamycin by transferring antibiotic resistance to gut-living bacteria. But, after years of scrutiny, Flavr Savr tomato (Redenbaugh *et al.*, 1992) was approved by the US Food and Drug Administration (FDA) in May 1994, thus making it the world's first genetically engineered whole food to reach US consumers (Holden, 1994). Some of the important groups of genetically modified tomato cultivars are: Earliana, Bonny Best, Marglobe, Stone, and Pink. Earliana var.

^(b)Aldehyde-alcohol dehydrogenase gene

is characterized by ripening early and its bright red fruits. Bonney Best has medium-sized, round to oblate, deep red fruit with a high incidence of cracking and scalding. The Marglobe variety is tolerant to *Fusarium* wilt, heavy yielding, with bright red, medium to large fruits. It is considered good for canning in the United States. Stone is grown extensively for canning and has scarlet-red, flattened, and firm fruits. The fruits of Pink are large, globose or heart shaped to irregular in shape, purplish pink to pinkish red with few seeds, low acidity, and have a pleasant flavor.

Selectable marker genes are used to discriminate between transgenic and nontransgenic cells and facilitate the identification of plants containing

co-transformed transgenes. The most common selectable markers and reporter genes are listed in Tables 1 and 2.

2. DEVELOPMENT OF TRANSGENIC TOMATOES

2.1 Transgenic Tomatoes *vis-a-vis* Ripening Phenomenon

A summary of studies conducted to manipulate ripening, fruit texture, flavor, and nutritional quality of tomato fruit using transgenic approach is presented in Table 3.

2.1.1 Cell wall carbohydrases, deoxyhypusine synthase, and fruit softening

Textural properties of tomato fruits are important contributors to the overall quality of fresh market fruits and to the properties of products processed from tomatoes (Barrett *et al.*, 1998). Because cell wall disassembly in ripening fruit contributes to fruit texture, modification of cell wall proteins and enzymatic activity during ripening can impact cell wall polysaccharide metabolism and influence texture. Transgenic tomato lines in which the expression of single or multiple genes

was altered have been developed (Carrington *et al.*, 1993; Brummell *et al.*, 1999a, b). A major focus on altering ripening characteristics arose with the isolation of the tomato fruit PG gene whose transcripts represent ~1% of ripening fruit messenger-RNA (mRNA). Both antisense repression (Smith *et al.*, 1988) and ectopic expression in unripe fruit (Giovannoni *et al.*, 1989) indicated that PG alone is not sufficient for softening. Nevertheless, a reduction in the susceptibility of ripe fruit to postharvest pathogens in antisense PG fruit led to the commercialization, though transiently, of PG antisense tomatoes.

Removal by pectin methylesterase (PME) of the methyl groups from pectins located in the fruit cell walls facilitates access of PG to its substrate. PME is expressed early in ripening and is down-regulated as ripening advances. Repression of tomato fruit PME via antisense technology resulted in increased juice viscosity attributable to the retention of the pectin chain length; however, softening was not altered significantly as compared with the wild type, nontransgenic tomato fruit (Tieman *et al.*, 1992; Tieman and Handa, 1994; Tieman *et al.*, 1995). The molecular weights of pectins isolated from processed juice were much higher from the transgenic fruit than the control fruit even under a cold break, indicating a role of pectin demethoxylation in pectin breakdown. Depending on the processing conditions, juice from these transgenic fruits contained 30–50% higher amounts of total uronic acids and had 25–250% higher degree of methoxylation (DOM) compared to juice from control fruits (Handa *et al.*, 1996; Thakur *et al.*, 1996).

In addition to PG and PME enzymes, several hemicellulose-metabolizing enzymes have been characterized in ripening fruit. Repression of the ripening-related endo- β -1,4-glucanases (also known as EGases or cellulases), *CEL1* and *CEL2*, altered pedicel and fruit abscission, respectively, but did not influence fruit softening (Lashbrook *et al.*, 1998a; Brummell *et al.*, 1999a). However, a ripening-related and ethylene-inducible tomato β -galactosidase gene, *TBG4*, was shown to have a role in fruit softening when its expression was repressed via antisense (Smith *et al.*, 2002). Similar role for the ripening-related expansin, *LeExp1*, was elucidated using similar approach (Rose *et al.*, 1997; Brummell *et al.*, 1999b).

Overexpression of the ripening-related *LeExp1* in tomato resulted in enhanced fruit softening (Barrett *et al.*, 1998; Powell and Bennett, 2002; Kalamaki *et al.*, 2003a). In contrast, suppression of expansin protein accumulation to about 3% of wild-type levels resulted in fruits with a firmer texture (Brummell *et al.*, 1999b; Kalamaki *et al.*, 2003a). Kalamaki *et al.* (2003b) showed that *LeExp1* overexpression resulted in higher juice viscosity and paste prepared from the transgenic fruits as compared to the control tomato fruit or the transgenic fruits with reduced *LeExp1* expression. These data indicated that *LeExp1*

overexpression enhanced depolymerization of water-soluble pectins as well as tightly bound matrix glycans.

Genes encoding β -galactosidase belong to a family of at least seven members of glycosyl hydrolases that reduce the levels of cell wall galactosyl residues in ripening tomato fruit (Carey *et al.*, 2001). Among these β -galactosidase (*TBG*) genes, *TBG6* shows the highest expression levels, but only at the mature green stage, prior to the development of visible signs of ripening (Smith and Gross, 2000). Moctezuma *et al.* (2003) reported that antisense suppression of *TBG6* in tomato increases fruit cracking, suggesting an important role for these enzymes in early tomato fruit growth and development.

Invertases (β -fructofuranosidase) are enzymes that hydrolyze Suc to Glc and Fru. In tomato, acid invertase activity is active during fruit ripening, and hexose sugars stored in the vacuole are the primary storage carbohydrate (Manning and Maw, 1975). Primary transformants with a chimeric, antisense acid invertase gene (*TIV1*) resulted in Suc accumulation in ripe fruit (Ohyama *et al.*, 1995). The constitutive expression of the *TIV1* antisense resulted in elevated levels of Suc but smaller fruit size and elevated ethylene production rates in T₁ transgenic plants (Klann *et al.*, 1996). These reports suggest that genetic modification of a single invertase gene has the potential of altering soluble sugar composition in tomato fruit. Interestingly, Chengappa *et al.* (1999) expressed the antisense sucrose synthase gene under the control of a fruit-specific promoter. In the young fruit of the transgenic tomato plants, sucrose synthase activity was reduced by up to 99% without affecting starch or sugar accumulation.

Deoxyhypusine synthase (DHS) mediates the first of two sequential enzymatic reactions that post-translationally modify eukaryotic translation initiation factor-5A (eIF-5A) with spermidine that becomes the unusual amino acid, deoxyhypusine. Constitutively suppressing *DHS* gene in tomato resulted in transgenic plants whose fruit ripened normally but exhibited delayed postharvest softening and senescence (Wang *et al.*, 2005). The transgene expression caused pleiotropic effects: male sterility, larger and thicker leaves that accumulated chlorophyll, higher activity of photosystem II, and enhanced starch deposition in the stems.

2.1.2 Targeting ethylene biosynthesis or its receptors

Ethylene is a simple gaseous plant hormone that has profound effects on plant growth and development (Mattoo and Suttle, 1991; Abeles *et al.*, 1992). Its role in fruit ripening has been genetically established (Theologis, 1992). Enzymes that regulate ethylene biosynthesis in plants are: S-adenosylmethionine (SAM) synthase, 1-aminocyclopropane-1-carboxylate (ACC) synthase, and ACC oxidase (Fluhr and Mattoo, 1996; Mattoo and Handa, 2004). The genes encoding these enzymes (Hamilton *et al.*, 1990; Oeller *et al.*, 1991) as well as those that metabolize SAM or ACC (Klee *et al.*, 1991; Good *et al.*, 1994) have been targeted in order to manipulate ethylene biosynthesis and thereby to regulate fruit ripening (Figure 1; see also Table 3). From these studies, it has been elegantly demonstrated that ethylene is the ripening hormone and that modulation of ethylene biosynthesis using genetic engineering can yield fruits with predictable characteristics.

To investigate the transcriptional regulation of two ACC oxidase genes in peach, Rasori *et al.* (2003) created constructs in which the ACC oxidase promoters, *PpACO1* and *PpACO2*, were used to drive the expression of β -glucuronidase (*GUS*) gene. These constructs were introduced into tomato (cv. Microtom). It was found that both promoters were active in tomato. *PpACO1-GUS* promoter activity was localized in leaf blade, ovary, leaf, fruit abscission zones, and pericarp, being up-regulated by propylene and wounding. Using a transient activity assay with peach fruit and constructs created by deleting different sections of the *PpACO1* promoter region, it was possible to find a region located between -716 and -346 bp, containing an ethylene-responsive element. Furthermore, two auxin responsive elements located upstream of the ethylene responsive elements were found. *PpACO2-GUS* promoter activity was found in vascular bundles of small and ripe fruit, senescent leaf blade, fruit and leaf abscission zones. The transformation of tomato for the expression of an apple antisense ACC oxidase led to reduced production of ethylene in the transgenic tomato fruit. Thus, tomato is a good crop model for testing specific ripening-related genes from heterologous species (Bolitho *et al.*, 1997).

The first characterization of an ethylene receptor gene from *Arabidopsis*, *AtETR1*, responsible for a dominant ethylene insensitivity showing many similarities with the two-component regulators in yeast and bacteria (Chang *et al.*, 1993), was another landmark discovery that virtually opened the area of research on ethylene signaling for genetic dissection as well as for biotechnological manipulations. Subsequently, the ethylene receptor gene family in tomato was found to consist of six members *LeERT1-LeETR6* (Wilkinson *et al.*, 1995; Zhou *et al.*, 1996a, b; Lashbrook *et al.*, 1998b; Tieman and Klee, 1999; Klee and Tieman, 2002). Each of the receptor genes has a distinct pattern of expression throughout development and in response to external stimuli. For instance, *LeERT1* and *LeETR2* are constitutively expressed in all tissues throughout development with *LeETR1* expression is about five times that of *LeETR2*. Results of a study that employed *LeERT1* antisense expression in tomato showed that the negative regulation model of ethylene receptors in ethylene signaling may not apply to ethylene-regulated abscission (Whitelaw *et al.*, 2002). The amino acid sequences of *LeERT1* and *LeERT2* protein are more closely related to *ERT1* of *Arabidopsis*, are highly similar to each other, and are constitutively expressed in all tomato tissues throughout development (Zhou *et al.*, 1996a, b; Lashbrook *et al.*, 1998b). However, their functional significance in ethylene receptor family is still unclear. With the goal to determine the effect of *LeETR1* and *LeETR2* specifically in the ethylene receptor family in tomato on ethylene signaling, Wang *et al.* (2006) generated two transgenic lines of tomato, ale1 and ale2, by introducing the antisense copy of *LeERT1* or *LeERT2* separately. A cross of ale1 and ale2 lines produced a line that had a phenotype similar to the ale1 in many aspects, which suggested that *LeERT1* plays a role in ethylene signaling of tomato growth and development.

In *Arabidopsis*, ethylene-insensitive 3 (*EIN3*) gene encodes a transcription factor that functions downstream from the ethylene receptors in the ethylene signal transduction pathway. Homologs of the *Arabidopsis EIN3* gene are present in tomato: *LeEIL*, *LeEIL1*, *LeEIL2*, and *LeEIL3*. Chen *et al.* (2004a) fused *EIL1* with green fluorescence protein (GFP) and induced its expression constitutively in the ethylene-insensitive

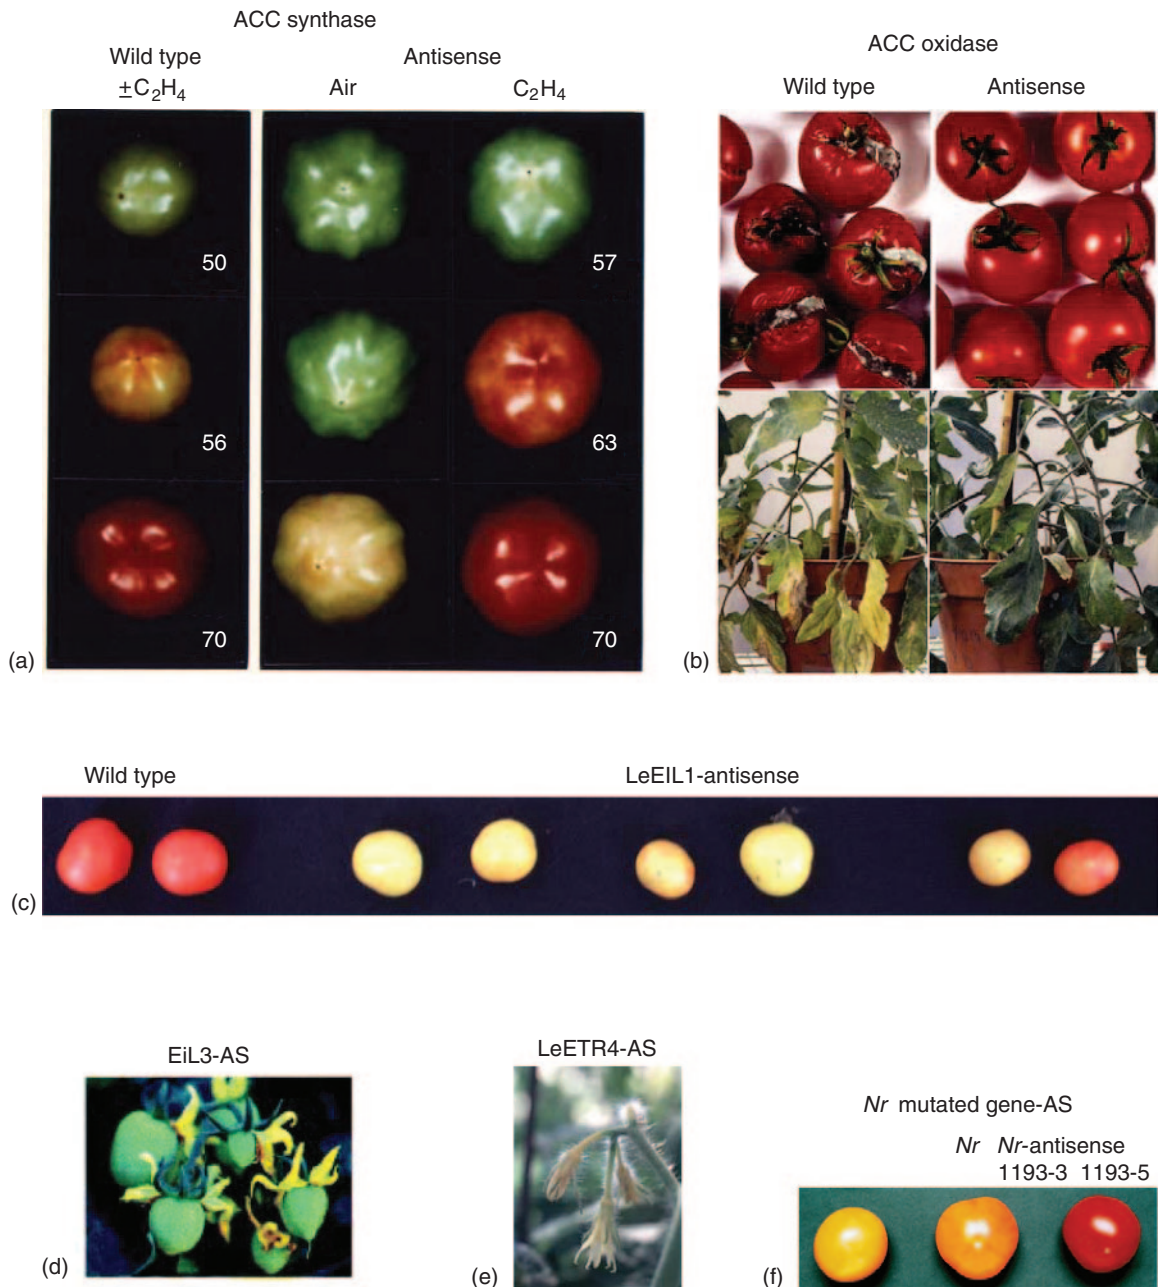

Figure 1 Reverse genetics studies that established the role of ACC synthase, ACC oxidase, ethylene-insensitive 3 like tomato homologs (LeEIL1 and LeEIL3) transcription factors, ethylene receptor LeETR4, and ethylene receptor NR in fruit ripening. Shown are the phenotypes obtained: (a) fruit ripening in the presence and absence of ethylene treatment after introduction of an antisense gene for ACC synthase (Oeller *et al.*, 1991), (b) senescence of tomato fruits and leaves following inhibition of ACC oxidase by its antisense gene (Picton *et al.*, 1993; John *et al.*, 1995), (c) fruit ripening in LeEIL1 antisense plants (Tieman *et al.*, 2001), (d) flower abscission in LeEIL3 antisense plants (Tieman *et al.*, 2001), (e) flower senescence in LeETR4 antisense (Tieman *et al.*, 2000), and (f) restoration of fruit ripening in Never-ripe (*Nr*) mutant by knocking out expression of the mutated ethylene receptor by its antisense (Hackett *et al.*, 2000). We thank Prof. Athanasios Theologis, Prof. Don Grierson, Prof. Harry Klee, and Dr. Denise Tieman for the original photographs of the illustrations shown here

tomato mutant Nr. The chimeric protein was found localized in the nuclei of the transgenic tomato fruit cells, and its overexpression induced a phenotype similar to the wild-type plants. Thus, this work emphasized the importance of using the Nr genetic background in studies to understand the ethylene-signaling pathway in tomato.

2.1.3 Tomato fruit quality

Tomato fruit and its processed products are the principal dietary sources of carotenoids such as lycopene. Lycopene is a potent antioxidant with the potential to prevent epithelial cancers and improve human health. Therefore, there is considerable interest to elevate the levels of carotenoids in tomato fruit by genetic manipulation and thereby improve the nutritional quality of the crop (Fraser *et al.*, 2002; Mehta *et al.*, 2002). It was shown that the constitutive expression of phytoene synthase 1 (*Psy-1*) in transgenic tomato resulted in a number of pleiotropic effects, including dwarfism due to diversion of geranylgeranyl diphosphate (GGPP) away from gibberellin biosynthesis (Fray *et al.*, 1995). Further work demonstrated that the use of regulatable promoters with heterologous genes could override the endogenous regulation and enable accumulation of higher levels of carotenoids in a fruit-specific manner. Thus, Mehta *et al.* (2002) developed transgenic tomatoes by introducing yeast SAM decarboxylase fused to the ripening-inducible promoter E8, and the transgenic fruits accumulated polyamines spermidine (Spd) and spermine (Spm) at the cost of the diamine putrescine. The independent homozygous lines accumulated lycopene levels that were two to three times higher than the nontransformed or azygous control and the fruit juice quality of the transgenics was improved by 50%. In another study, bacterial phytoene synthase was fused to the tomato PG promoter and overexpressed in Ailsa Craig (Fraser *et al.*, 2002). The fruits from the resulting transformants showed higher levels of carotenoids, phytoene, lycopene, β -carotene, and lutein. The biosynthetically related isoprenoids, tocopherols, plastoquinone, and ubiquinone, and the activities of isopentenyl diphosphate isomerase, geranylgeranyl diphosphate synthase, and incorporation of isopentenyl diphosphate into phytoene were not significantly altered.

Engineering the accumulation of higher polyamines, Spd and Spm, in tomato fruit enabled nuclear magnetic resonance (NMR) spectroscopic analysis for profiling distinct metabolite trends in the transgenic and wild-type/azygous fruits ripened off the vine (Mattoo *et al.*, 2006). Gln, Asn, choline, citrate, fumarate, malate, and an unidentified compound A also accumulated in the red transgenic fruit while the levels of Val, Asp, sucrose, and glucose were significantly reduced as compared to the control (wild type and azygous) red fruit. Specificity of these changes was apparent since the levels of Ile, Glu, γ -aminobutyric acid (GABA), Phe, and fructose remained similar in the nontransgenic and transgenic fruits. Mattoo *et al.* (2006) suggested that the pathways involved in the nitrogen sensing/signaling and carbon metabolism are targeted when higher levels of Spd/Spm accumulate in the fruit. These results also demonstrated that fruit cells can metabolize amino acid pathways late in fruit ripening independent of the parent plant.

Flavonoids are polyphenols whose dietary intake has the potential to prevent chronic diseases. Schijlen *et al.* (2006) introduced heterologous, flavonoid pathway genes—stilbene synthase, chalcone synthase, chalcone reductase, chalcone isomerase, and flavone synthase, to produce novel flavonoids in tomato fruit. These novel flavonoids—flavones and flavonols—increased threefold, mostly in the peel that was found to have higher total antioxidant capacity. These findings add further credence to the potential of engineering tomato fruit for accumulation of high levels of beneficial nutrients.

The first successful study conducted to engineer the taste of tomato fruit involved transformation of tomato with the thaumatin gene from the African plant “katemfe” (Bartoszewski *et al.*, 2003). Thaumatin is a sweet-tasting protein. Fruit from T₂ transgenic plants tasted sweeter than the control plants, leaving a unique and sweet-specific aftertaste.

The volatile aroma compounds are essential for good flavor in tomato (Baldwin *et al.*, 2000). The tomato genome contains two genes potentially encoding carotenoid cleavage dioxygenases, *LeCCD1A* and *LeCCD1B*; *LeCCD1B* being highly expressed in the ripening fruit. Antisense expression of *LeCCD1B* gene in tomato reduced transcripts for both the genes in leaves

and fruits. Further, the transgenic lines were found to have reduced levels of volatiles β -ionone and geranylacetone, suggesting the importance of these genes in the production of tomato volatiles (Simkin *et al.*, 2004). A similar approach was used by Tieman *et al.* (2006) to overexpress *LeAADC1A* and *LeAADC2* in tomato, which led to a 10-fold increase in the emission of volatiles, 2-phenylacetaldehyde and 2-phenylethanol. The antisense-mediated reduction of *LeAADC2* gene significantly decreased the emission of these volatiles.

Chen *et al.* (2004b) reported the identification of a specific isoform of tomato lipoxygenase, *TomloxC*, involved in the generation of fatty acid-derived flavor components. Sense and antisense constructs of *TomloxC* were designed and introduced in tomato plant. The transgenic plants in which *TomloxC* transcripts were reduced showed a reduction in the flavor volatiles including hexenal, hexanal, and hexanol. Thus, this gene is another candidate for manipulation of aroma/flavor of tomato fruit.

2.2 Transgenic Tomatoes Resistant or Tolerant to Biotic Stresses

The increasing importance of integrated pest management, largely as a result of concerns over environmental quality and food safety, together with the failure of conventional chemicals due to the development of increasing number of insecticide-resistant species has provided a major niche for deploying the potential of insecticidal proteins such as *Bacillus thuringiensis* (*Bt*) in protection against insects (Dent, 1993; Marron, 1993; Forrester, 1994). The cry protein toxins have enormous commercial potential as safe, biodegradable pesticides. What is particularly important is that a biopesticide is specific to the insect and does not affect aquatic or forest ecosystems where other beneficial and nontarget insect must be conserved (May, 1993). In 1909, Berliner had isolated a sporulating bacterium from diseased mediterranean flour moth larvae he received from a mill in Thuringen. He named the bacterium, *Bt*, from which the toxin protein called *Bt* was first used as an insecticide in the early 1930s, primarily against the European corn borer (*Ostrinia nubilalis*) in Southeast Europe.

The first commercial product (spreine) was available in 1938 in France (Weiser, 1986) for the control of the flour moth (Jacobs, 1951). In 1960, stimulated by the growing concern over the use of chemical insecticides, the first *Bt* strain was commercialized and was marketed as "Thuricide."

Genetic engineering of disease resistance by transferring defence-related genes or pathogen-origin genes into crops has economic value as well as maintaining an eco-friendly environment by cutting the costs and reducing the pesticide usage (Shah, 1997; Salmeron and Vernooij, 1998; Rommens and Kishore, 2000; Stuiver and Custers, 2001). In cotton alone the introduction of *Bt* has resulted in reduction of over 95 million kilograms of pesticide use worldwide in the first 10 years of commercial use (Brookes and Barfoot, 2006). Since insect infestation causes significant losses in tomato, it is likely that the genetic engineering approaches have the potential to substantially reduce pesticide use in tomato and other vegetable crops. Likewise, much more reduction in the overall pesticide use is anticipated by engineering vegetable crops to resist various viral, fungal, and bacterial pathogens. Significant progress has been made in developing resistance to biotic stress in all major crops including tomato.

2.2.1 Insect infestation

Table 4 lists genes that represent a variety of functional activities and which have been used to engineer insect resistance in tomato. These include *Bt* (Cry1Ac), proteinase inhibitors, expansin, arginase, threonine deaminase, sarcotoxin1 A, plant lectin; Mi-1.2 protein, a member of the nucleotide-binding leucine-rich repeat (NB-LRR) protein, and carboxypeptidases. However, only in limited cases efficacy of the introduced genes has been field evaluated for resistance trait (Rhim *et al.*, 1995). Until such studies are performed, the utility of these genes or the putative "insect-resistant" plants will remain obscure.

Tomato plants transformed with a crystal δ -endotoxin gene encoding a coleopteran insect-specific toxin from *Bacillus thuringiensis* subsp. *tenebrionis* (*B.t.t.*) were shown to express a 74 kD protein that cross-reacted with *Bt* toxin antibodies. These transgenic plants exhibited a

significant insecticidal activity when challenged with Colorado potato beetle larvae (Rhim *et al.*, 1995). A synthetic *cry1Ac Bt* gene was introduced into tomato plants using *Agrobacterium*-mediated transformation (Mandaokar *et al.*, 2000) and high levels of *Bt* expression in the leaves of transgenic plants were ascertained by enzyme-linked immunosorbent assay (ELISA). The transformed plant leaves and fruits were found resistant to the larvae of tomato fruit borer (*Helicoverpa armigera*). The limited field trail of T₁ generation was successful in demonstrating resistance against *H. armigera*.

Constitutive expression of a prosystemin antisense gene in tomato resulted in about three times higher growth rates of *Manduca sexta* (tobacco hornworm) larvae feeding on transgenic plants

compared with nontransformed control plants (Orozcocardenas *et al.*, 1993). In the leaves of antisense transgenic tomato plants, proteinase inhibitors I and II were undetectable until the 6th day of larval feeding before exhibiting an increase throughout the plants reaching over 100 mg g⁻¹ of leaf tissue after 14 days. In the nontransformed control plants, in comparison, a rapid increase in both proteinase inhibitors occurred from the second day of larval feeding reaching over 225 mg g⁻¹ of leaf tissue by the 8th day. These results offered the first evidence showing that plant resistance against an insect pest can be genetically modulated by molecular engineering.

In order to evaluate whether or not a combination of two anti-insect genes will be

synergistic in preventing insect infestation, Abdeen *et al.* (2005) overexpressed two different potato protease inhibitors, the serine-proteinase inhibitor PI-II and the carboxypeptidase inhibitor (PCI) in tomato plants. Serine proteases (trypsin and chymotrypsinlike) are the main midgut proteases of *H. armigera* and *Heliothis virescens* while carboxypeptidases have also been identified (Katherine, 1995; Bown *et al.*, 1998). Leaf-specific overexpression of the PI-II and PCI resulted in increased resistance to *Heliothis obsoleta* and *Liriomyza trifolii* larvae in homozygous tomato lines expressing high levels (>1% the total soluble proteins) of the transgenes. However, leaf damage in hemizygous lines for these transformants was more severe than in controls. The experiment suggested that the combined expression of defence genes with different mechanisms of action rather than combination of inhibitors may be more effective in overcoming the general adaptive response of the insects. Tomato proteinase inhibitor II genes (*tin2*, *tin2i*) when transformed into tobacco showed that the tobacco transformants carrying *tin2i* sequence were more resistant to 2-instar larvae of *Heliothis armigera* Hubner than those carrying the *tin2* sequence. Therefore, the intron of *tin2i* sequence may contribute to the insecticidal activity of the transgenic tobacco. A proteinaceous aspartic proteinase inhibitor, designated as tomato chymotrypsin inhibitor 21 (*TCI21*), was expressed in tomato and found to increase mortality and delay growth of Egyptian cotton worm (*Spodoptera littoralis*) (Lison *et al.*, 2006).

Chen *et al.* (2005) used a mass spectrometry-based approach to identify host proteins that accumulate in the midgut of *M. sexta* larvae reared on tomato plants. They showed that two jasmonate-inducible proteins, arginase and threonine deaminase, act in the *M. sexta* midgut to catabolize the essential amino acids arginine and threonine, respectively. Transgenic plants overexpressing arginase were more resistant to *M. sexta* larvae, and this effect correlated with reduced levels of midgut arginine. This work demonstrated that the jasmonate signaling pathway strongly influences the midgut protein content of phytophagous insects and further supports the hypothesis that amino acid catabolism in the insect digestive tract by host enzymes plays a role in plant protection against herbivores.

The parasitism of root-knot nematode (*Meloidogyne javanica*) was controlled when the antisense expansin *LeEXPPA5* was expressed in tomato gall cells adjacent to the nematode feeding cells. It was concluded that the reduced expansin expression reduced the ability of the nematode to complete its life cycle in transgenic roots (Gal *et al.*, 2006). The effect of ingestion of transgenic tomato leaves expressing the plant lectin *Galanthus nivalis* agglutinin (GNA) on development of larvae of *Lacanobia oleracea* (Linnaeus) was studied by Wakefield *et al.* (2006). They reported that when *L. oleracea* larvae were fed on tomato line 14.1H expressing approximately 2.0% GNA, significant increases in the mean larval weight and in the amount of food consumed were found. Examination of the effects of ingestion of tomato leaves expressing GNA on the development of the tomato moth, *L. oleracea*, showed that larvae grew larger, developed more quickly, and consumed more plant material than larvae fed on untransformed tomato leaves. Also, survival of *L. oleracea* to the adult stage was much reduced on untransformed tomato leaf compared to previously published figures for survival on untransformed potato leaf and artificial diet (Bell *et al.*, 2001). In a further series of experiments the effects of GNA ingestion by the host larvae on the development and survival of the solitary endoparasitoid *Meteorus gyrator* were evaluated. Life history parameters examined for development of *M. gyrator* in hosts reared on transgenic or nontransgenic diets were not significantly altered, regardless of the time period until when the host was maintained on the diet. The authors suggested that *M. gyrator* is not particularly sensitive to GNA present in the host.

Transformation of a susceptible tomato cv. Moneymaker with the *Mi-1.2* gene resulted in resistance to nematodes and aphids (Goggin *et al.*, 2006). The *Mi-1.2* locus confers resistance against root-knot nematodes (*Meloidogyne* spp.), the potato aphid (*Macrosiphum euphorbiae*), and the sweet potato whitefly (*Bemisia tabaci*). This locus was introgressed into cultivated tomato about 60 years ago through a cross with a wild tomato species, *Solanum peruvianum* (syn. *L. peruvianum*) (Smith, 1944). The *Mi-1.2* protein is a member of the NB-LRR class of plant resistance genes. Interestingly, when the same chimeric gene construct was used to transform a susceptible

variety of eggplant, the transgenic lines displayed resistance to the root-knot nematode *M. javanica* but were fully susceptible to the potato aphid indicating involvement of additional genes in aphid resistance.

Transgenic tomato plants expressing the sarco-toxin IA gene were grown either in polyethylene (PE) bags or in pots inoculated with *Orobanche aegyptiaca* seeds. Transgenic plants exhibited strong inhibition of parasite growth and significantly increased yield as compared with nontransgenic ones. In both PE and pot systems, most of the parasite tubercles attached to the transgenic root plants turned necrotic and developed abnormally. These results indicate that the insect gene produced in the plant cells was selectively toxic to the parasite and not the host plant (Radi *et al.*, 2006).

Lawrence and Novak (2006) used a recombinant potato virus X (PVX), carrying a gene for chitinase, WIN6, to infect tomato plants. The leaves from infected plants were tested for insecticidal properties on Colorado potato beetle (CPB; *Leptinotarsa decemlineata* (Say)). Less than half of CPB neonates feeding on leaves containing >0.3% w/w WIN6 developed to 2nd instar compared to 93% on control uninfected leaves. These results confirmed the role of chitinases in providing resistance against insects and other pathogens (Kumar *et al.*, 2004).

2.2.2 Fungal pathogens

Plants are constantly exposed to various kinds of microbes, which derive nutrition from them. To overcome the pathogen infestation, plants have evolved both broad-spectrum and species-specific mechanisms. As a part of defence strategy plants produce low-molecular-weight compounds and proteins that inhibit the growth of phytopathogenic fungi. In recent years, significant understanding of host–pathogen interactions has led to the characterization of specific genes that play a role in disease establishment. A number of antimicrobial proteins (typically consisting of ~100 amino acid residues) and polypeptides (around 30–60 amino acid residues) have been identified (Veronese *et al.*, 2003). Additionally, pathways leading to production of various antifungal compounds, such as phytoalexins, have been characterized (Morrissey and Osbourn, 1999).

Although some of these genes have been expressed in transgenic tomato to enhance tolerance to fungal pathogens (see a summary in Table 5), new targets will emerge from further understanding of the interactions between plants and their fungal pathogens (Maor and Shirasu, 2005).

Phytoalexins are a class of chemicals that are implicated in plant's defence responses by acting as toxins to invading phytopathogens. They represent several classes of chemicals including alkaloids, terpenoids, and glycosteroids. This plant defensive arsenal is generally induced in plants when they confront a pathogen attack. Stilbene synthase produces the phytoalexin transresveratrol. Thomzik *et al.* (1997) transformed tomato with two stilbene synthase genes from grapevine (*Vitis vinifera*) and characterized the transgenic plants for stable integration and expression of the transgene, and finally tolerance of the transgenics to *P. infestans*. The authors reported that both the introduced genes were stably maintained and expressed in transgenic regenerants. Upon fungal inoculation, transgenic plants accumulated the phytoalexin transresveratrol, the product of stilbene synthase, and exhibited increased resistance to *P. infestans*. Inoculation of transgenic tomato with *Botrytis cinerea* and *Alternaria solani* also caused accumulation of resveratrol but plants did not show significant resistance to these fungi.

Schaefer *et al.* (2005) introduced genes coding for an iris ribosomal-inactivating protein (I-RIP), a maize β -glucanase (M-GLU), and a *Mirabilis jalapa* antimicrobial peptide (Mj-AMP1) into tomato. Selected transgenic lines were inoculated with a suspension containing $2\text{--}3 \times 10^4$ conidial spores/ml of the fungal pathogen *A. solani*, the causal agent of tomato early blight. Compared to parental control, two transgenic lines carrying either M-GLU or Mj-AMP1 showed enhanced resistance to early blight disease. None of the four lines carrying the I-RIP transgene showed resistance to early blight.

A synergistic effect of a tobacco class I chitinase and β -1,3-glucanase genes in planta was first demonstrated by Jongedijk *et al.* (1995). The double transformants showed a 36–58% reduction in disease severity when infected with *F. oxysporum* f. sp. *lycopersici*. The transgenic tomato plants expressing either one of these genes were not protected against fungal infection. Tabaeizadeh

et al. (1999) observed the effect of constitutive expression of an acidic endochitinase gene, *pcht28*, from *Lycopersicon chilense* for resistance against *V. dahliae*. The R_1 plants evaluated in the greenhouse for tolerance to *V. dahliae* race 1, 2 and R_2 plants against race 2 showed a significantly ($P < 0.05$) higher level of tolerance to the fungi compared to the nontransgenic plants. The resistance was demonstrated by foliar disease symptoms and vascular discoloration index.

Honee *et al.* (1995) reported the potential use of avirulence genes in tomato and tobacco. They reconstructed Avr9 from the tomato fungal pathogen *C. fulvum*, pAVIR1, pAVIR2, and pAVIR21, respectively encoding the wild-type AVR9 protein and two hybrid AVR9 proteins containing the signal sequences of the

pathogenesis-related proteins PR-S and PR-1a. The Cf0 genotypes of tomato, with construct pAVIR21, showed a normal phenotype.

Hevein, a protein from rubber tree (*Hevea brasiliensis*), is composed of one chitin-binding domain and a C-terminal polypeptide homologous to PR proteins such as tobacco PR-4 and tomato P2 proteins. Constitutive expression of mature hevein in tomato resulted in retardation of growth of *Trichoderma hamatum* in transgenic plants (Lee and Raikhel, 1995).

Heterologous expression of pear fruit polygalacturonase inhibitor protein (pPGIP) resulted in abundant accumulation of (PGIP) in all tissues and did not alter the expression of an endogenous tomato fruit PGIP (Powell *et al.*, 2000). The growth of *B. cinerea* on ripe tomato

fruit expressing pPGIP was reduced, and tissue breakdown was diminished by as much as 15% as compared with nontransgenic fruit. However, in an earlier investigation Desiderio *et al.* (1997) characterized different PGIPs from *Phaseolus vulgaris* and reported that *P. vulgaris* produces several PGIPs with different specificities for various phytopathogenic fungi. These authors also reported that the high-level expression of *PGIP-1*, a member of the *PGIP* gene family, in transgenic tomato plants is not sufficient to confer enhanced resistance to either *F. oxysporum* f. sp. *lycopersici*, *B. cinerea*, or *A. solani*. More work is needed to characterize PGIP produced in different species to identify genes with generalized resistance to various phytopathogenic fungi.

Oxalic acid is used by several phytopathogenic fungi in their attack on plants. Therefore, research was done to overexpress oxalate decarboxylase from *Collybia velutipes* in transgenic tobacco and tomato both of which developed resistance to fungal infection. These transgenic tobacco and tomato plants showed remarkable resistance to phytopathogenic fungus *Sclerotinia sclerotiorum* that utilizes oxalic acid during infestation (Kesarwani *et al.*, 2000).

The *Arabidopsis* thionin (*Thi2.1*) gene was used to genetically engineer enhanced resistance to multiple diseases in tomato. A construct was created in which the fruit-inactive promoter RB7

was used to control the expression of the *Thi2.1* gene. In transgenic lines containing *RB7/Thi2.1*, constitutive *Thi2.1* expression was detected in roots and a little in leaves, but not in fruits. Disease assays revealed that the transgenic lines tested showed enhanced resistance to bacterial wilt (BW) and *Fusarium* wilt (FW). It was found that BW disease progression in transgenic lines was delayed by a systemic suppression of bacterial multiplication (Chan *et al.*, 2005).

2.2.3 Bacterial pathogens

Table 6 summarizes seminal studies on developing resistance against bacterial pathogens. The tomato disease resistance (*R*) gene *Pto* encodes a serine/threonine protein kinase that is postulated to be activated by a physical interaction with the *AvrPto* protein. It also specifies race-specific resistance to the bacterial pathogen *P. syringae* pv. *tomato* carrying the *avrPto* gene. Overexpression of *Pto* under the cauliflower mosaic virus (CaMV) 35S promoter resulted in microscopic cell death, salicylic acid accumulation, and increased expression of PR genes indicating activation of defence responses in the absence of the *Pto-AvrPto* interaction. Only the palisade mesophyll cells exhibited cell death that required light for induction. Mesophyll

cells expressing *Pto* showed accumulation of autofluorescent compounds, callose deposition, and lignification. The transgenic tomato plants exhibited significant resistance to *P. syringae* without *avrPto* and reduced bacterial growth than did nontransgenic lines. These transgenics also showed more resistance to *Xanthomonas campestris* pv. *vesicatoria* and *C. fulvum*. Taken together, these results provided evidence that overexpression of an *R* gene can activate defence responses and general resistance to bacterial pathogens (Tang *et al.*, 1999).

A cationic iron-binding glycoprotein, lactoferrin (LF), was tested for developing transgenic tomatoes resistant to bacterial-wilt-causing *Ralstonia solanacearum* Smith. R_1 and R_2 transgenic lines inoculated with race 1 exhibited early resistance and subsequent susceptibility, while 44–55% of plants survived until fruit maturity (Lee *et al.*, 2002).

Thipyapong *et al.* (2004) introduced a chimeric antisense of the polyphenol oxidase enzyme (PPO) complementary-DNA (cDNA) into tomato. It was found that all members of the *PPO* gene family were down-regulated. Down-regulation of *PPO* in antisense plants did not affect growth, development, or reproduction of greenhouse grown plants. However, antisense *PPO* expression dramatically increased susceptibility to *P. syringae*, suggesting a critical role for PPO-catalyzed phenolic oxidation in limiting disease development in tomato.

Seong *et al.* (2007) have previously isolated a *Capsicum annuum* pathogenesis induced factor (CaPIF1) from pepper leaves after infection with the soybean pathogen *Xanthomonas axonopodis* pv. *glycines* 8ra. Overexpression of *CaPIF1*, which encodes a Cys-2/His-2 zinc finger transcription factor, resulted in major transcriptional modulation without exhibiting any visual morphological abnormality. The up-regulated genes included those from various metabolic pathways, and stress and defence response categories. The transgenic plants exhibited tolerance to cold stress and to the bacterial pathogen *P. syringae* pv. *tomato* DC 3000, tolerance being correlated with the expression levels of *CaPIF1*. The authors suggested that *CaPIF1*, a plant-specific unique Cys-2/His-2 transcription factor, regulates expression of genes both directly and indirectly, leading to increased tolerance to biotic and abiotic stresses.

2.2.4 Viral pathogens

Substantial efforts have been made to engineer virus resistance in tomato plants. Table 7 lists some of the studies conducted and phenotypes obtained.

Whitefly transmitted geminiviruses are widely distributed in tropical and subtropical regions around the world, causing yield losses in important crops such as cassava, tomato, bean, cotton, and pepper (Brown and Bird, 1992; Polston and Anderson, 1997; Moriones and Navas-Castillo, 2000; Morales and Anderson, 2001). Fuentes *et al.* (2006) developed transgenic tomato plants transformed with an intron–hairpin construct to induce post-transcriptional gene silencing in the geminivirus tomato yellow leaf curl virus (TYLCV) replication-associated protein gene (*CI*). The intron–hairpin RNA produced involved 726 bp of the 3' end of the TYLCV *CI* gene as the arms of the hairpin, and the castor bean catalase intron. Transgenic tomato plants belonging to line 126, harboring a single transgene copy, showed immunity to TYLCV, even in extreme conditions of infection such as 4-leaf-stage plants and from 300 up to many hundreds viruliferous whiteflies per plant during 60 days. In an earlier study, Brunetti *et al.* (1997) had shown that high expression of a truncated version of the *CI* gene of tomato yellow leaf curl geminivirus, encoding the first 210 amino acids of the multifunctional *rep* protein, confers resistance to TYLCV in transgenic tomato plants.

Motoyoshi and Ugaki (1993) reported the transformation (with a chimeric tobacco mosaic virus (TMV) coat protein gene under the control of the CaMV 35S promoter) of an F_1 hybrid between *L. esculentum* and *L. peruvianum*. Transgenic line 8804-150 accumulated 2.5 mg coat protein per gram fresh weight in fully developed fresh leaves and exhibited the strongest resistance to tomato mosaic virus (TOMV) among the plants examined. The transgenic plants did not show any morphologic or physiologic differences when compared to the nontransgenic control plants. The accumulation of the coat protein and associated higher resistance to TMV were found to be transmissible to the next generation. Xue *et al.* (1994) also successfully developed transgenic tomato plants expressing a high level of resistance to cucumber mosaic virus strains of subgroup-I and subgroup-II. These transgenic tomatoes

that are resistant to isolates from both subgroups of cucumber mosaic virus (CMV) have practical significance for controlling this serious disease.

Transgenic tomato plants exhibiting a broad commercial resistance to CMV infection have been developed by expressing coat protein (*CP*) genes from the CMV-D strain and two Italian subgroups CMV-22 of subgroup I and CMV-PG of subgroup II (Kaniewski *et al.*, 1999). Transgenic plants were selected based on *CMV CP* expression, resistance to CMV in segregating progenies, and presence of single transgene copy. Transgenic plants generated

using *CP* from any of the strains showed broad resistance against CMV strains from both the subgroups, I and II. These transgenic lines were field tested to assess the level of resistance and agronomic performance (Tomassoli *et al.*, 1999). Field evaluation was performed at multilocations in Italy where the target virus spread naturally by the indigenous aphid populations. Although these trials showed CMV resistance of the transgenic tomatoes under field conditions, resistance was less effective in the field than what was observed in growth chamber experiments. Transgenic tomato

plants expressing the *CP* gene of *Physalis mottle* tymovirus (PhMV) showed delay in symptom development indicating partial resistance to the virus (Vidya *et al.*, 2000).

Whitham *et al.* (1996) tested if resistance to pathogen found in other plant species can be transferred by transformation across interspecies barriers. These authors transformed tomato with *N* gene from tobacco. *N* genes possess a putative nucleotide binding site and leucine-rich repeats and confer a gene-for-gene resistance against the viral pathogen TMV and most other members of the tobamovirus family (Whitham *et al.*, 1994). Tomato transgenics expressing the *N* gene exhibit a hypersensitive response and effectively restricts TMV to the sites of inoculation, as in tobacco. These results showed that all the components necessary for *N*-mediated resistance are conserved in tomato. Thus, the utility of using resistance genes from a heterologous species to protect crop plants from diseases was demonstrated for the first time. A viral nucleoprotein (N) was shown to impart resistance to tomato spotted wilt virus when expressed in tomato (Fedorowicz *et al.*, 2005). These authors further reported that transgenic plants exhibited resistance to virus infection even in the absence of detectable levels of the translational product of the introduced gene.

The interspecific tomato hybrid, *L. esculentum* × *Lycopersicon pennellii* (F₁), sensitive to the TYLCV disease was successfully transformed with *TYLCV* gene encoding capsid protein (V1). The R₁ plants inoculated with *TYLCV* using whiteflies showed delayed disease symptoms and increased recovery from the disease (Kunik *et al.*, 1994). Transgenic (R₁ progeny) tomato plants expressing CMV satellite RNA fused to *GUS* gene when inoculated with virion or RNA preparations of CMV or tomato aspermy virus (TAV) showed mild disease symptoms in the first 2 weeks followed by a decrease in symptoms (McGarvey *et al.*, 1994). Subsequently, the transgenic and control plants were same by the 4th week. Along with *CP* genes, the role of movement protein (BVI and BCI) and truncated replicase (T-rep) in conferring viral resistance seems apparent (Gal-On *et al.*, 1998; Hou *et al.*, 2000; Nunome *et al.*, 2002; Antignus *et al.*, 2004). Likewise, *N* genes from tobacco and tomato spotted wilt virus (TSWV) have been used for viral tolerance (Whiteman

et al., 1996; Fedorowicz *et al.*, 2005). Field trials of transgenic tomato plants expressing an ameliorative satellite RNA of CMV exhibited mild or no CMV symptoms and low viral titers relative to nontransformed plants. When infected with CMV, the transgenic lines showed 40–84% greater total marketable yield compared to parent lines. A significant negative correlation between satellite RNA levels and disease severity was found in transgenic lines (Stommel *et al.*, 1998).

Tomato plants transformed with the *Arabidopsis NPR1* (nonexpresser of PR genes) gene showed heat tolerance and resistance to TMV. These transgenic lines had significant level of enhanced resistance to BW and FW, and moderate degree of enhanced resistance to gray leaf spot (GLS) and bacterial spot (BS). The enhanced disease-resistance was stably inherited. These transgenics open the possibility of transferring these characteristics into tomato cultivars with good agronomic and organoleptic characteristics (Lin *et al.*, 2004).

The D satellite RNA (satRNA) is a strain of CMV that induces an epidemic lethal disease by triggering programmed cell death (PCD). With the goal to control the disease, Xu *et al.* (2004) created transgenic tomato plants expressing animal antiapoptotic genes *bcl-xL* and *ced-9*. T₁ and T₂ generations of transgenic plants showed delayed cell death symptoms and absence of symptoms. The degree of symptom suppression was correlated with increased expression levels of the transgenes. More than 80% of the *bcl-xL* and *ced-9* T₁ transgenic lines showed higher survival rates than the average for the line G138A, generated by a loss of function mutation of a transgenic line carrying the *bcl-xL* gene. Total RNA extracted from surviving plants contained D satRNA, indicating systemic accumulation of D satRNA. Thus, expression of *bcl-xL* and *ced-9* improved tolerance, rather than resistance, to CMV/D satRNA infection. In addition, it was found that expression of *bcl-xL* and *ced-9* specifically abrogated the formation of necrotic lesions, but not the symptoms due to chilling at 4°C (abiotic stress). At 7°C, temperature-induced leaf senescence was dramatically delayed in *bcl-xL* and *ced-9* transgenic plants, and high levels of anthocyanins accumulated, possibly limiting oxidative stress. It was concluded that heterozygous expression of *bcl-xL* and *ced-9*

in tomato plants enhanced plant survival by inhibiting PCD induced by both biotic and abiotic stress, including virus infection and chilling. These transgenic plants not only provide a good system for plant PCD research but also have a potential value for agricultural applications.

2.3 Transgenic Tomatoes Resistant or Tolerant to Abiotic Stresses

Plants are sessile and because they are constantly exposed to vagaries of nature, they have developed fine responses to environmental extremes that in turn may impact their growth, productivity, and quality. Much work has been done on plant responses to environmental extremes such as high salinity, drought, cold and heat, heavy metals, hypoxia due to flooding, and oxidative stress. To confront these different abiotic stresses, plants have developed an elaborate signaling network that perceives these signals and modulates the expression of select genes (Zhang *et al.*, 2004). Significant progress has been made in understanding these pathways using *Arabidopsis* as a model system. However, a great effort has gone into developing tomato plants that can withstand different abiotic stresses. Table 8 summarizes some of these studies.

2.3.1 Drought tolerance

Plant response to water deficit is articulated in a complex network of morphological, physiological, and molecular changes. As plant's relative water content decreases, plant growth is slowed, and stomatal closure occurs, which is paralleled by a decreased photosynthetic rate (Lawlor, 2002). Emerging knowledge of processes involved in drought-stress adaptation will likely translate into crop varieties that can withstand drought without impacting crop productivity. A number of drought-responsive genes have been identified in various genetic screens using *Arabidopsis* as a model system. It is anticipated that development of tomato varieties tolerant to water deficits will not only increase the productivity of tomato in many regions of the world but also help in regaining more arable land. However, significant more work is needed before this knowledge can be translated

into developing desirable tomato varieties that can tolerate water stress.

Park *et al.* (2005) constitutively overexpressed the vacuolar H⁺-pyrophosphatase in commercial tomato varieties. The resulting transgenic plants exhibited greater pyrophosphate-driven cation transport into root vacuolar fractions, increased root biomass, and enhanced survivability under soil water deficit stress. Constitutive expression of *Arabidopsis CBF1* (C-repeat/dehydration-responsive element-binding factor 1) in tomato resulted in enhanced plant tolerance to cold, drought, and salt stresses. However, this enhanced tolerance came at a cost, causing reduced plant growth and yield (Hsieh *et al.*, 2002a, b). When the same gene (*CBF1*) was expressed using an abscisic acid (ABA)/stress-inducible promoter from barley *HAV22* gene, the transgenic tomatoes showed enhanced tolerance to chilling, water deficit, and salt stresses as compared to untransformed plants and the use of the inducible promoter eliminated the deleterious effects of the ectopic expression of *CBF1* on plant growth and yield (Lee *et al.*, 2003).

Boiling stable proteins (BSP) have been implicated in desiccation tolerance against water stress by protecting proteins. Transgenic tomato plants transformed with a novel 66-kD BSP from *Populus tremula* were tested for drought tolerance by polyethylene glycol (PEG) test, biomass analysis, proline estimation, and electrolyte leakage measurement. These plants exhibited slightly increased tolerance to water stress compared to the parental genotype (Roy *et al.*, 2006).

Linker histone proteins are induced by environmental conditions in many plant species playing a role as yet not elucidated. Two possible roles for H1-S histone have been proposed: a structural role in DNA protection from damage occurring during water deficit and a functional role in the regulation of gene expression (Scippa *et al.*, 2000). Scippa *et al.* (2004) developed transgenic tomato plants overexpressing antisense histone *H1-S*, which is a drought-induced linker histone of tomato. *H1-S* antisense transgenic plants developed normally indicating that H1-S does not play an important role in the basal functions of tomato development. However, the stem height of the transgenic lines was reduced by 30% compared with the wild type by a shortening in the stem internodes. Later in development, transgenic plants appeared to have a higher number of leaves than the wild type at the

Polyphenol oxidases	Potato	CaMV 35S:PPO sense or antisense	More favorable water relations, decreased photoinhibition, and higher chlorophyll levels in PPO-suppressed transgenic compared to overexpressed and untransformed plants after water stress indicating reduced photo-oxidative stress in PPO-suppressed lines	Thipyapong <i>et al.</i> , 2004
Catalase (katE)	<i>Escherichia coli</i>	RbcS3C:katE	Enhanced photo-oxidative stress tolerance	Mohamed <i>et al.</i> , 2003

same age. Also, differences between the wild type and antisense plants were observed in leaf anatomy and physiological activities. No differences were detected in chromatin organization, excluding a structural role for H1-S in chromatin organization. It was concluded that likely H1-S histone modulates mechanisms related to the stomatal function.

2.3.2 Salt stress tolerance

About one-fifth of the irrigated, agriculture land is impacted by salinity and it is rapidly expanding due to the increased use of underground water. Throughout its ontogeny, tomato, like most other crop plants, is sensitive to salinity (Foolad, 2004, 2007). Our limited understanding of molecular bases regulating salt tolerance in plants has hampered progress in developing salt-tolerant crops. Nonetheless, several genes with a potential role in imparting tolerance to salinity stress have been identified. These include calcium sensor protein, SOS3, which binds to and activates a Ser/Thr protein kinase SOS2 that regulates activities of a plasma membrane Na^+/H^+ antiporter SOS1, and a tonoplast Na^+/H^+ antiporter NHX1 (Sahi *et al.*, 2006). A putative osmosensory histidine kinase (AtHK1)-MAPK (mitogen activated protein kinase) cascade is another signaling pathway hypothesized to regulate osmotic homeostasis and reactive oxygen species (ROS) scavenging. It is expected that understanding of ion transporters and their regulators, and of the CBF (C-repeat-binding factor) regulons, will help in the future development of salt-tolerant crops (Chinnusamy *et al.*, 2005).

Zhang and Blumwald (2001) overexpressed the *Arabidopsis* *NHX1* vacuolar Na^+/H^+ antiporter in tomato plants. These transgenic plants were able to grow, flower, and produce fruit in the presence of 200 mM sodium chloride. Interestingly, their leaves accumulated high concentrations of sodium, but the transgenic fruits contained very low levels of sodium. Salt and other osmotic stresses have been shown to increase levels of glycine betaine, which is an important quaternary ammonium compound in many organisms. Betaine aldehyde dehydrogenase encoded by *BADH* gene catalyzes conversion of betaine aldehyde into glycine betaine. Overexpression of *BADH* gene from

sorghum contributed to maintenance of osmotic potential under salt stress (Moghaieb *et al.*, 2000). The tomato hairy root lines transformed with *BADH-1* gene using root inducing plasmid (pRi) plasmid accumulated betaine. Constitutive expression of *Atriplex hortensis* *BADH* gene in tomato led to enhanced tolerance of transgenic tomato to salt stress (Jia *et al.*, 2003).

Overexpression of yeast *HAL1* in transgenic tomatoes, which is involved in the regulation of K^+ transport, also imparted tolerance to high levels of salt. Like the yeast, these transgenic tomatoes were able to maintain higher levels of K^+ and decreased levels of intracellular Na^+ than the control (Gisbert *et al.*, 2000), suggesting similarities between these transgenic plants and yeast as far as the mechanisms that regulate salt tolerance are concerned. Accumulation of a nonreducing disaccharide of glucose, trehalose, has been implicated in plant tolerance to different stresses. Transgenic tomato plants transformed with yeast trehalose-6-phosphate synthase (*TPS1*) gene exhibited improved tolerance to drought, salt, and oxidative stress indicating a great potential of this gene to impart stress tolerance to plants (Cortina and Culianez-Macia, 2005).

2.3.3 Temperature stress tolerance

Plants vary in their responses to temperature extremes. Apart from stress due to freezing temperatures, nonfreezing low temperatures cause chilling injury while high temperatures impair crop productivity (Iba, 2002). Tomato is highly sensitive to all these. Freezing tolerance of tomato is limited to -2 to -3°C whereas extended storage at temperatures below 12°C results in severe chilling injury-related physiological disorder that also affects fruit ripening. Tomato fruit kept at a temperature of 30°C and above show abnormal ripening including lack of lycopene accumulation, slow down in chlorophyll degradation and tissue softening, and decrease in ethylene production (Biggs *et al.*, 1988; Picton and Grierson, 1988). Heat-exposed fruit upon return to moderate temperatures recover and start ripening, at least partially, but there is a delay in the overall ripening process (Biggs *et al.*, 1988; Kagan Zur *et al.*, 1995). Steady-state transcript levels and enzyme activity of several ripening-related genes, including

ACC synthase, ACC oxidase, and PG, decrease in tomato fruit stored at 35°C (Biggs *et al.*, 1988; Picton and Grierson, 1988; Kagan Zur *et al.*, 1995). Expression of PG, an enzyme implicated in fruit softening, is gradually and irreversibly impaired in fruit at elevated temperatures (Kagan Zur *et al.*, 1995). Symptoms of chilling injuries are reduced after heat treatment, and this reduction is correlated with persistence of several heat shock proteins, HSPs, in the fruit tissue (Sabeheh *et al.*, 1998).

In response to a sudden exposure to heat, most organisms including plants synthesize a set of proteins, designated as HSPs. Based on molecular size, HSPs have been classified into five classes (Hsp100, Hsp90, Hsp70, Hsp60, and a family of small HSPs ranging between 17 and 43 kD). HSPs act as molecular chaperones to facilitate protein folding, transport and maturation, and protect other proteins from heat-induced aggregation. The conservation of the primary structure of HSPs and ubiquitous expression in all organisms led to the hypothesis that these proteins play protective roles against heat stress by maintaining homeostasis. A short exposure to temperatures of 38–40°C causes transient induction of HSPs transcription in plants. A number of heat shock activated transcription factors (HSFs) are present in plant genomes and are characterized by binding to the *cis*-elements (heat shock elements; HSEs) present at the 5'-flanking regions of the HSPs. More work is needed to understand the role of HSPs in plant adaptation to high temperatures in order to use them for developing heat-tolerant plants (Iba, 2002).

To evaluate the role of chloroplast small HSPs, Neta-Sharir *et al.* (2005) overexpressed tomato *HSP21* under the CaMV 35S promoter. Characterization of the resulting transgenic plants revealed that chloroplastic *HSP21* protected photosystem II (PSII) from temperature-dependent oxidative stress but did not as such affect the thermotolerance. These authors also provided evidence of the protein's role in fruit reddening and the conversion of chloroplasts to chromoplasts. Interestingly, the expression of chloroplastic *HSP21* substituted for the heat treatment via the accumulation of carotenoids in fruits stored for 2 weeks at 2°C and then transferred to room temperature. These authors suggested that in addition to a protective role under

stress conditions, *HSP21* plays a role in plant development under normal growth conditions.

Ramakrishna *et al.* (2003) have cloned from tomato a novel small HSP gene designated as viscosity 1 (*vis1*). This protein plays a role in pectin depolymerization and juice viscosity of ripening fruits. *vis1* is regulated by the fruit ripening process and high temperature. It exhibits a typical HSP chaperone function when expressed in bacterial cells. Interestingly, in nontransgenic tomato genotypes, expression of *vis1* is negatively associated with juice viscosity. Deng and Handa (unpublished results) developed tomato lines expressing both antisense and sense chimeric genes under the control of CaMV 35S. Field evaluation of these plants revealed that reduction in *vis1* expression accelerated accumulation of carotenoids while its overexpression delayed their accumulation. Also, ectopic expression of *vis1* increased viscosity of the processed tomato fruit juice (Deng and Handa, unpublished results).

Transgenic tomato plants that express antisense of *LeHSP100* exhibited reduced tolerance to heat stress (Yang *et al.*, 2006). These transgenic plants were not able to express *LeHSP100/ClpB* upon exposure to heat and the plants withered within 21 days of the recovery period at normal temperature following a "lethal" heat shock at 46°C for 2 h. In contrast, the untransformed control plants and the vector-transformed plants survived. These results show that *LeHSP100/ClpB* contributes to the acquisition of thermotolerance in higher plants. Nautiyal *et al.* (2005) developed transgenic tomato lines overexpressing tomato *MT-sHSP* and showed that vegetative tissues of T₀ and T₁ lines exhibited enhanced thermotolerance.

Yi *et al.* (2006) have characterized 1.9 kb of 5'-flanking region of *Lehsp23.8* by expressing GUS under its control in transgenic tomato plants. These authors reported that GUS expression was seen in the roots, leaves, flowers, fruits, and germinated seeds after heat shock but the heat inducibility was different at various developmental stages. In fruit tissues, the heat-induced GUS activity was higher in the pericarp followed by placenta and lowest in the locular gel. Unlike *vis1* (a ripening-induced shsp) that showed much higher heat inducibility in ripening fruit (Ramakrishna *et al.*, 2003), maximum heat inducibility of GUS under the *Lehsp23.8* promoter was observed in green fruit. The promoter of

Lehsp23.8 was also induced by cold, exogenous ABA, and heavy metals (Cd^{2+} , Cu^{2+} , Pb^{2+} , or Zn^{2+}).

Characterization of transgenic tomato plants over and underexpressing the heat stress transcription factor *HsfA1* revealed no difference in their major developmental parameters under normal growth conditions compared to wild-type plants (Mishra *et al.*, 2002). However, *HsfA1* underexpressing plants as well as their fruits exhibited extreme sensitivity to elevated temperatures. Co-silencing of *HsfA1* by its transgenes resulted in reduced heat stress-induced accumulation of chaperones and Hsfs suggesting a unique function of *HsfA1* as a master regulator for inducing thermotolerance. The effect of heat shock factor (Hsf) on chilling tolerance has also been studied by expressing *AtHsA1b* and *gusA* under CaMV 35S promoter. The transformed tomato showed more accumulation of heat shock-induced gene transcripts and enzymes including a twofold increase in the specific activity of soluble isoforms of ascorbate peroxidase (Li *et al.*, 2003).

The function of endoplasmic reticulum (ER)-located small heat shock proteins (ER-sHSPs) in ER stress was tested by Zhao *et al.* (2007) by overexpressing *LeHSP21.5* in tomato plants. ER stress is basically an imbalance between the cellular demand for protein synthesis and the capacity of the ER to promote protein maturation and transport, which leads to an accumulation of unfolded or misfolded proteins in the ER lumen. Gene expression in the transgenic lines greatly attenuated the lethal effect of tunicamycin (a potent inducer of ER stress) on tomato seedlings. Moreover, tunicamycin treatment led to lower levels of the chaperone-binding protein, protein disulfide isomerase, and the chaperone calnexin transcripts in transgenic tomato plants than the nontransgenic tomato plants. These results suggest that the HSP *LeHSP21.5* can alleviate the tunicamycin-induced ER stress by promoting proper protein folding.

Plants from tropical regions, such as tomato, maize, and rice, are unable to tolerate freezing and suffer chilling injury when exposed to temperatures in the range of 0–12°C (Zhang *et al.*, 2004). Expression of a number of genes is altered in plants exposed to low temperatures. A variety of stress-responsive transcriptional factors that regulate the signal transduction network

underlying perception of stress response have been identified (Yamaguchi-Shinozaki and Shinozaki, 2006). Some of the components of the complex cascade of gene expression under cold stress have been engineered into tomato to determine their effect on cold tolerance including freezing.

Transformation of tomato (cv. Moneymaker) with a chloroplast targeted *codA* gene of *Arthrobacter globiformis*, which encodes choline oxidase that catalyzes the conversion of choline to glycine betaine, improved chilling and oxidative stress tolerance of transgenic plants (Park *et al.*, 2004). Transgenic tomato plants accumulated up to 1.2 mM of glycine betaine per gram of fresh weight with the chloroplasts containing up to 86% of total leaf glycine betaine. These transgenic tomato lines produced 10–30% more fruit compared to untransformed plant. As mentioned above, overexpression of *Arabidopsis CBF1/DREB1B*, especially driven by three copies of an ABA-responsive complex (*ABRC1*) from the barley *HAV22* gene, resulted in enhanced tolerance in tomato to chilling, water deficit, and salt stress (Hsieh *et al.*, 2002a; Lee *et al.*, 2003). Seong *et al.* (2007) reported that overexpression of *CaPIF1* enhanced tolerance to cold stress and bacterial pathogen *P. syringae* pv. *tomato* DC 3000. These authors further reported that the enhanced tolerance was correlated with *CaPIF1* expression levels in transgenic plants. However, underexpression of a catalase gene or overexpressing an *Escherichia coli* glutathione reductase did not alter chilling sensitivity of transgenic tomatoes (Bruggemann *et al.*, 1999; Kerdnaimongkol and Woodson, 1999).

Although significant progress has been made in identifying components of freezing tolerance in *Arabidopsis*, limited success has been obtained in engineering any tolerance to this stress in tomato (Zhang *et al.*, 2004). Constitutive overexpression of either *LeCBF1* or *AtCBF3* in transgenic tomato plants was ineffective in increasing freezing tolerance. Transcript analysis using a tomato microarray with 8000 genes revealed only 4 genes whose expression was over 2.5-fold up-regulated in the *LeCBF1* or *AtCBF3* overexpressing transgenic tomato lines. Three of these genes were up-regulated in response to low temperature. These authors reported that although tomato has a CBF cold response pathway, it is much smaller and less diverse in function compared to that of

Arabidopsis. Overexpression of *DEAL*, a circadian-regulated tomato gene that showed sequence similarity to an *Arabidopsis* cold protection gene, *EARLII*, did not alter cold susceptibility of transgenic tomato (Weyman *et al.*, 2006).

2.3.4 Tolerance to hypoxia

Anaerobic conditions (anaerobiosis) occur during waterlogging, flooding, poor drainage, or even during irrigation causing oxygen deficiency, anoxia with bare minimum oxygen availability, and hypoxia with only some oxygen availability in the rooting zone. Plants respond to anaerobiosis in a variety of ways. Increase in the rate of glycolysis and fermentation occurs to compensate for the decrease in energy and lack of nicotinamide adenine dinucleotide (NADH) regeneration. In the root apical meristem, cell survival is important for the plant development. Metabolic changes under anoxia help maintain cell survival by generation of adenosine 5'-triphosphate (ATP) anaerobically and minimization of cytoplasmic acidosis associated with cell death. Hypoxia causes loss in crop productivity by depressing growth and yield of dryland species (Drew, 1997). In the fully expanded cells behind the root apex, hypoxic conditions result in the formation of continuous, gas-filled channels (aerenchyma) carrying O₂ from the leaves. A bacterial ACC deaminase under the transcriptional control of double CaMV 35S, the *rolD* promoter from *Agrobacterium rhizogenes* (root-specific expression), enabled tomato plants with increased tolerance to flooding stress and lesser deleterious effects of root hypoxia on plant growth than the nontransformed plants (Grichko and Glick, 2001). Plant attributes evaluated in this study included shoot height, fresh and dry weight, epinasty, ACC deaminase activity, ethylene production, and leaf chlorophyll and protein contents.

To determine if increased hexokinase (HXK) activity alters hypoxic metabolism in roots, Gharbi *et al.* (2007) overexpressed *Arabidopsis* and *Saccharomyces cerevisiae* HXKs in tomato. Wild type and *ScHXX2* transgenic tomatoes showed a decline in the adenylate energy status after 2 days of hypoxic treatment, with a further decrease occurring by 7 days in roots, but these did not happen in *AtHXX1* transgenic lines. Increase in

sucrose synthase activity that occurs in wild-type plants under hypoxia was not seen in transgenic tomato overexpressing *AtHXX1*.

2.3.5 Oxidative stress tolerance

Most environmental stresses including high salinity, drought, and temperature extremes result in generation of ROS causing oxidative stress in plants. Molecular engineering of plants by altering expression of genes involved in these stress responses also resulted in their altered response to oxidative stress. The genes used include: *CBF* (cor-binding-factors) that regulate expression of *cor* (cold-regulated) genes (Hsieh *et al.*, 2002b; Lee *et al.*, 2003), *HSP21* (Neta-Sharir *et al.*, 2005), and *choline oxidase* (Park *et al.*, 2004).

The role of PPO has also been examined by its overexpression and suppression using transgenic approach (Thipyapong *et al.*, 2004). PPOs have been implicated in photoreduction of molecular oxygen by photosystem I (PSI) in the Mehler reaction. Transgenic tomato plants with suppressed PPO showed more favorable water relations and decreased photoinhibition compared to transgenic plants overexpressing PPO or the untransformed control plants. Higher chlorophyll levels were observed in water-stressed, PPO-suppressed transgenics compared to PPO-overexpressed and untransformed plants indicating reduced photooxidative stress in PPO-suppressed lines.

Transgenic tomato overexpressing an *E. coli* catalase (*katE*) gene under tomato *Rubisco* small subunit gene promoter showed approximately threefold higher catalase activity than that the wild-type plants (Mohamed *et al.*, 2003). The transgenic plants exhibited higher tolerance to 100 μ M paraquat under high light illumination than wild-type plants. Leaf discs from transgenic lines remained green and had reduced ion leakage at 24 h after treatment with paraquat than the discs from nontransgenic plants. Photosynthesis (determined by the Fv/Fm ratio) and catalase activity were less impaired by paraquat in transgenic compared to wild-type tomato plants. Collectively, the transgenic plants exhibited increased tolerance to the oxidative damage caused by drought stress or chilling stress under high light intensity. Previously, the expression of antisense catalase

gene (*ASTOMCAT1*) in “Ohio 8245” enhanced susceptibility to oxidative stress and chilling injury in transgenic tomato plants (Kerdnaimongkol and Woodson, 1999). Leaf catalase activity was lowered by twofold to eightfold with a concomitant twofold increase in H_2O_2 levels. Treatment of these transgenic plants with 3% H_2O_2 resulted in visible damage during first 24 h leading ultimately to death while the wild type and azygous control plants recovered from the treatment. These studies indicate that overexpression of catalase is a promising way to develop transgenic plants that can withstand photo-oxidative stress.

2.4 Vaccines and Clinical Applications

The potential use of transgenic plants as bioreactors is now well established. Plants offer several advantages in comparison to other expression systems, including low-cost inputs, feasibility of scaling-up, reduction of health risks deriving from contamination with human pathogens, simplification of downstream or upstream processing and, most importantly, plant cells are able to perform complex post-translational modifications (Daniell *et al.*, 2001; Walmsley and Arntzen, 2003). A wide variety of pharmaceutically valuable proteins that fall into three major categories have been produced in plants: antibodies (Vaquero *et al.*, 1999; Stoger *et al.*, 2000), antigens (Chikwamba *et al.*, 2002; Jani *et al.*, 2002; Bouche *et al.*, 2003), and biopharmaceuticals that fully retain their activity (Magnuson *et al.*, 1998; Mor *et al.*, 2001; Zhang *et al.*, 2003).

Research for using plants to express and deliver oral vaccines has attracted much attention. This is mainly because this strategy offers several advantages over vaccine delivery by injection. Oral vaccines also offer the hope of more convenient immunization strategies and a more practical means of implementing universal vaccination programs worldwide. Oral vaccines acts by stimulating the immune system at effector site (lymphoid tissue) located in the gut. Curtiss and Cardineau (1990) first reported the expression of *Streptococcus mutans* surface protein antigen A (SpaA) in tobacco. Since then, a great progress has been made (Ma *et al.*, 2001). So far, more than 10 viral epitopes and subunits of bacterial toxins have been successfully expressed in plants,

including hepatitis B surface antigen (HBsAg) (Mason *et al.*, 1992; Gao *et al.*, 2003), *E. coli* heat-labile enterotoxin B subunit (LTB) (Haq *et al.*, 1995; Streatfield *et al.*, 2001), cholera toxin B subunit (CT-B) (Arakawa *et al.*, 1998), Norwalk virus capsid protein (Mason *et al.*, 1996; Tacket *et al.*, 2000), and rabies virus glycoprotein (McGarvey *et al.*, 1995).

Tomato is one of the fruits tested for expression of vaccines. McGarvey *et al.* (1995) engineered tomato (cv. UC82b) plants to express a gene encoding a glycoprotein (G-protein), which coats the outer surface of the rabies virus. The recombinant constructs contained the G-protein gene from the environmental risk assessment (ERA) strain of rabies virus. The G-protein was expressed in leaves and fruit of the transgenic plants and it was found localized in Golgi bodies, vesicles, plasmalemma, and cell walls of vascular parenchyma cells.

Ma *et al.* (2003) overexpressed hepatitis E virus (HEV) open reading frame 2 partial gene in tomato plants, to investigate its expression in transformants, the immunoactivity of expressed products, and explore the feasibility of developing a new type of plant-derived HEV oral vaccine. The recombinant protein was produced at 61.22 ng g^{-1} fresh weight in fruits and $6.37\text{--}47.9 \text{ ng g}^{-1}$ fresh weight in the leaves of the transformants. It was concluded that the *HEV-E2* gene was correctly expressed in transgenic tomatoes and that the recombinant antigen derived had normal immunoactivity. These transgenic tomato plants are a valuable tool for the development of edible oral vaccines.

Gutierrez-Ortega *et al.* (2005) reported the expression of functional interleukin-12 (*IL-12*) from mouse in transgenic tomato plants with a construct in which the expression of the single-chain mouse *IL-12* was controlled by the CaMV 35S promoter. They showed that the *IL-12* accumulated up to 7.3 and $3.4 \mu\text{g g}^{-1}$ of fresh weight in leaves and fruits, respectively. The mouse *IL-12* expressed in tomato was shown to have immunomodulatory function *in vitro*, as determined by interferon- γ (IFN- γ) secretion by T cells.

Vaccination against anthrax is considered the most promising strategy to combat the disease. The expression in plants of the protective antigen (PA) encoded by the gene *pagA* is thought

to be a good approach to generate an edible vaccine against anthrax. Aziz *et al.* (2005) reported the successful expression of a functional PA in tomato. The integration of the *pagA* gene in the tomato nuclear genome was verified by polymerase chain reaction (PCR) and Southern analysis. The fidelity of PA protein expression in transgenic tomato plants was confirmed by the detection of a single protein of 83 kD by anti-PA polyclonal antibodies at a maximum dilution of 1:200. Transgenic tomato plants did not show phenotypic aberrations although they were found to be more sensitive to fluctuations in temperature and humidity when compared with the wild type.

The Gram-negative bacterium *Yersinia pestis* is the causative agent of plague, affecting human health since ancient times. It is still endemic in Africa, Asia, and the Americas. Due to the increasing reports of incidence, antibiotic resistance strains and concern with the use of *Y. pestis* as an agent of biological warfare, there is the urgent need for a safe and cheap vaccine. Out of all the *Y. pestis* antigens tested, only F1 and V induce a good protective immune response against a challenge with the bacterium (Benner *et al.*, 1999). The F1 (Fraction 1) antigen is the major capsular protein. It forms a polymer composed of a protein subunit and plays an important role in inhibiting phagocytosis by macrophages (Du *et al.*, 2002). The V antigen is a secreted protein that regulates the translocation of the cytotoxic effector proteins from the bacterium into the cytosol of mammalian cells. Alvarez *et al.* (2006) reported the expression in tomato of the *Y. pestis* F1-V antigen fusion protein. The immunogenicity of the F1-V transgenic tomatoes was confirmed in mice that were injected subcutaneously with bacterially produced F1-V fusion protein and boosted orally with transgenic tomato fruit. Expression of the plague antigens in the tomato fruit allowed producing an oral vaccine candidate without protein purification and with minimal processing technology, offering a good system for a great scale vaccination program.

The vaccinia virus B5 protein is a component of a subunit vaccine against smallpox but the employment of a live vaccine displays some side effects. Golovkin *et al.* (2007) successfully tested two plant expression systems to produce recombinant B5 antigenic domain. The plant-derived B5 antigen was purified and administered

parenterally and intranasally to mice. The mice thus vaccinated showed protection when challenged with a live vaccinia virus.

2.5 Improving the Environment by Using Transgenic Tomatoes

Transgenic plants can be used to have positive effects on the environment through bioremediation. Bioremediation is attracting importance as an alternative technology for the elimination of pollutants in soil and water. This is an effective, environmentally nondestructive and cheap method based on the use of green plants to remove, contain, or transform toxic chemicals into harmless one (Tengerdy and Szakacs, 1998; Suresh and Ravishankar, 2004). This technique has been tested with some success to remove polynitrated aromatic compounds, which are part of explosives (French *et al.*, 1999; Rosser *et al.*, 2001; Ramos *et al.*, 2005), toxic heavy metals (Kramer and Chardonnens, 2001; Singh *et al.*, 2003; Eapen and D'Souza, 2005), and arsenic (Alkorta *et al.*, 2004).

Cover crop mulches, particularly of plants capable of fixing nitrogen (e.g., *Vicia villosa* Roth) (HV), have been shown to enhance productivity and quality of the crop subsequently grown on them and these benefits include: retention of longevity and greenness in the leaves (Teasdale and Abdul-Baki, 1997; Kumar *et al.*, 2004), less pest infestation, and enhanced tolerance or resistance to disease (Mills *et al.*, 2002). Economically, this alternative system is sustainable and superior over the conventional system (Kelly *et al.*, 1995; Lu *et al.*, 2000). The desirable performance of hairy vetch (HV) mulch-grown vegetables has presented an opportunity to explore the kind of genes regulated by this production system. Tomatoes grown in a HV cover crop possess a highly organized and specific network system of genes that remain actively expressed for longer duration than the plants grown in black PE or rye mulch. These genes include: *rubisco* (ribulose-1, 5-bisphosphate carboxylase/oxygenase), a protein essential for photosynthesis and N remobilization; glutamine synthetase (*GS*), which plays a major role in N conversion and C utilization for the synthesis of amino acids, the building blocks for all proteins; and ATPase, chlorophyll-binding proteins in the chloroplast, *cytb₅₅₉*, and plastocyanin,

all important for photosynthesis and converting harvested chemical energy into food. These studies validate the use of alternative production system based on leguminous cover crop mulches, making it possible for the same or reduced inputs to produce greater outputs, something that agriculturalists generally desire (Kumar *et al.*, 2004; Mattoo and Abdul-Baki, 2006). These results also bring to the fore the importance of genotype \times environment ($G \times E$) interactions in determining beneficial attributes in plants. It opens possibilities for evoking from crop plants a more productive response not by adding external inputs but by altering their growing conditions.

An integrated model has been developed in our laboratory. This model is based on comparative performance/metabolism of transgenic tomato genotypes grown in N-fixing leguminous HV mulch, nonleguminous rye mulch, and black polyethylene (BP) mulch. We suggest that this integration holds the promise of value addition to crops, benefit to the environment by decreasing chemical input, preserving agricultural land as well as reducing economic burden on the farmer. Significant genotype \times mulch-dependent interactions affecting plant phenotype and fruit characteristics were revealed and exemplified by 20 fruit metabolites profiles, and expression patterns of the *ySAMdc* transgene and tomato *SAMdc* and *E8* genes in fruits, between a nontransgenic (556AZ) and transgenic (579HO) line accumulating higher polyamines. These studies have demonstrated that HV mulch enables a metabolic system in tomato akin to the one in higher polyamines-accumulating transgenic fruit that have higher phytonutrient content (Neelam *et al.*, 2008).

2.6 Utilization of Transgenic Tomatoes to Improve Human Health

Transgenic plants can potentially bring several positive effects and improve human health by:

1. Reducing the use of chemicals, herbicides, and pesticides, can improve the environment and make the ecosystem friendlier.
2. Development of functional foods with better nutritional composition:
 - a. Increased concentration of the phenolic chlorogenic acid (Niggeweg *et al.*, 2004).
 - b. Transgenics with long chain polyunsaturated fatty acids such as linolenic acid,

arachidonic, eicosapentaenoic acid, and docosahexaenoic acid (Huang *et al.*, 2004; Wu *et al.*, 2005; Truksa *et al.*, 2006), thochromanols (Kinney *et al.*, 2006), conjugated linoleic acid (Khono-Murase *et al.*, 2006).

- c. Enhanced provitamin A β -carotene (Sautter *et al.*, 2006), vitamins A, E, and C (Herbers, 2003), and trace elements (Sautter *et al.*, 2006).
- d. Increased amount of the antioxidant resveratrol (Lim *et al.*, 2005).
- e. Increase in the levels of ascorbate and glutathione, the soluble antioxidants of primary metabolism, as well as in the total antioxidant activity (Giovinazzo *et al.*, 2005).
- f. Foods with high amounts of potent antioxidants: flavonoids, lycopene (Mehta *et al.*, 2002; Ravanello *et al.*, 2003; Davuluri *et al.*, 2005).
- g. Antibodies-producing transgenics for diagnostics, prevention, and treatment of diseases (Fischer *et al.*, 2003).
- h. Recombinant proteins with correct pharmacological characteristics such as human LF protein (Rachmawati *et al.*, 2005; Taylor and Ramsay, 2005).

2.7 Intellectual Property and Regulatory Requirements for the Release of Genetically Modified Tomato Varieties

Development and release of genetically modified crops are complex issues involving diverse players including inventors, institutions/industry, and government agencies that control releases. Additionally, biologists and general public play important roles in consumer acceptance and successful use of a new transgenic plant variety. Multiple technologies involving various biological discoveries are needed to develop a new crop variety. The cost of acquiring technology tied up in intellectual properties has become a substantial barrier to the development and commercialization of genetically engineered crops. A long list of regulatory hurdles had to be crossed for the historic release of "Flavr Savr", a tomato variety that harbored an antisense gene of a PG (Kramer and Redenbaugh, 1994). The benefits and concerns of development and release of transgenic

Table 9 Biotechnology patents—issued for various improvements in tomato^(a)

Term	Number of patents
Tomato	
Tomato	12064
Tomato fruit	5223
Tomato gene	4796
Tomato gene AND chimeric	3130
Tomato transgenic	3926

^(a)Data are based on US Patent Collection database search conducted on April 23, 2007 using indicated terms for each search. All terms were used with “AND” except tolerance and resistance that were used with “OR” as indicated in the table. These searches should be interpreted with caution as some entries may show up due to nonspecific search term(s) present in the text, especially in the cited references. In general, the number of patents is expected to be less than shown in this table

horticulture crops have been reviewed (Delmer *et al.*, 2003; Clark *et al.*, 2004; Redenbaugh and McHughen, 2004; Bradford *et al.*, 2005).

Despite the availability of many genes and regulatory sequences to improve various desirable attributes, commercialization of genetically modified crops has seriously lagged world over.

This situation also applies to the development of GM tomato. As discussed in this chapter, impressive numbers of genes with potential to enhance tomato crop productivity and nutritional aspects have been identified and characterized. Table 9 presents a partial list of the numerous patents granted to studies for improvement of both

crop productivity and fruit quality in tomato using genetic engineering.

Pioneering work done by Calgene to evaluate safety of transgenic “Flavr Savr” tomato variety for its unregulated release status has greatly contributed to testing of transgenic tomato under field conditions (Redenbaugh *et al.*, 1992). For most tomato transgenic lines, submission of a Letter of Notification is sufficient. However, a full Animal and Plant Health Inspection Service (APHIS) permit is required for transgenic tomatoes that express any plant pest structural sequences: http://www.aphis.usda.gov/biotechnology/permits_main.shtml.

3. THE FUTURE: EXPECTED TECHNOLOGIES

Transgenic crops including tomato have the potential to promote revolutionary change in agriculture, industry, nutrition, and even medicine. By manipulating plant genomes, crops can be engineered to provide enhanced nutritional value with in-built resistance to biotic and abiotic stresses, plant raw materials adapted to the requirements of industry, and “green factories” to produce a host of novel products, including pharmaceuticals, in an environmentally benign and sustainable manner (Halpin, 2005).

Progress toward “output trait” products with nutritional, environmental, or other benefits that consumers can directly appreciate has been slow. It can be enhanced and time shortened by removing or working around the bottlenecks of developing technologies for the coordinated manipulation of multiple genes or traits. This bottleneck is perhaps not widely appreciated, but is amply evidenced by the huge body of literature describing the manipulation or expression of single, useful genes in plants, and the comparative paucity of publications dealing with the manipulation of multiple genes or master genes. Yet, the advantages of “stacking” or “pyramiding” existing GM traits in crops are obvious, and offer the potential for providing durable multiresistance to particular pests or for engineering multiple resistance to different types of pathogen, perhaps in crops that are also herbicide tolerant. Similarly, the potential for sophisticated metabolic engineering in plants is enormous, and could lead to the development of

plants able to grow in inhospitable environments, which might provide healthier foodstuffs or improved raw materials.

The recent inroads toward systems biology incorporating features from transcriptome, proteome, lipidome, glycome, and metabolome should provide novel “nodes” whose modification may result in multiple attributes being affected by manipulations involving controls via master switches for major or minor secondary metabolic pathways. It is recognized that most metabolic processes that are targets for manipulation depend on the interaction between numerous genes, and flux through biochemical pathways often coordinated with that of competing pathways; therefore, effective metabolic engineering will only be achieved by controlling multiple genes on the same, or interconnected, pathways. The current predominant stacked trait crops are insect-resistant and herbicide-tolerant maize and cotton. Over the past few years significant advances in multigene manipulation have been made using a variety of conventional and novel techniques that, despite imperfections, provide a framework for future improvements (Halpin, 2005).

1. INTRODUCTION

The eggplant, *Solanum melongena* L. ($2n = 24$), belongs to the family Solanaceae (the nightshade or potato family), which also includes other important vegetables like potato, tomato, and red peppers. The eggplant has different names in different countries. For example, it is known as “aubergine” in France, “melanzana” in Italy, “eggfruit” in Australia, and “brinjal” in India. It is an important nontuberous vegetable and widely cultivated in many parts of the world, especially Asia, Africa, central America, Mediterranean area, and South of the United States (Sihachakr *et al.*, 1993; Collonnier *et al.*, 2001a). About 1.75 million hectares were cultivated in 2005 in the world for a total production of 30.4 million tons, of which 91.5% of the world production was contributed by Asia (FAO, 2005). The crop requires a relatively long season of warm weather to give good yields, and thus the tropical and subtropical climate is ideal for its cultivation, although it is grown in some parts of the temperate region as well.

The eggplant is generally considered as a “low calorie vegetable”. However, eggplant’s nutritional value is comparable to most of the other common vegetables. It contains vitamins, minerals, proteins, fiber, and also important phytonutrients like phenolic compounds and flavonoids, many of which have antioxidant activity. Besides, eggplant has been used in the traditional medicines. Its tissue extracts are used for the treatment of asthma, bronchitis, cholera, and dysuria and fruits and leaves are beneficial in lowering blood cholesterol. Recently, it has been shown that eggplants also possess antimutagenic properties (Khan, 1979; Hinata, 1986; Kalloo, 1993; Collonnier *et al.*, 2001a; Kashyap *et al.*, 2003; Rajam and Kumar, 2006)

The cultivated eggplant is morphologically similar to a number of taxa (Bhaduri, 1951). It belongs to the nontuberiferous group of species of *Solanum*. In addition to the primitive cultivars and the wild species of *Solanum incanum*, a number of other putative wild varieties and species have been described one time or another. Cultivated varieties of eggplant can usually be easily distinguished

from the remainder of the taxa comprising the eggplant complex by their enlarged and often purple fruit and almost complete lack of prickles on the stem, leaves, and calyx. It is also easy to distinguish members of the eggplant complex from other *Solanum* species. It is an erect or prostrate, branched herb or shrub, about 1 meter tall, wooly or scurfy and spiny, but the spines are inconspicuous in some cultivated varieties. The leaves are large, ovate or oblong ovate, shallowly sinuate lobed, becoming nearly glabrous above but remaining densely tomentose beneath, the flowers are large and mostly in clusters. The calyx is wooly and often spiny, persistent, and accrescent. The spreading, lobed, purplish corolla is 2.5 cm or more in diameter. Heterostyly is a common feature. The fruit is a large berry, showing great varieties in size, shape, and color. It may be oblong, obovoid, ellipsoid, egg shaped, more or less spherical, cylindrical, elongate, etc. The color may be almost black, various shades of purple from dark to very light, blue, green, yellowish, striped variously, or white, ripening to brown, or orange.

Germplasm resources and collections have been well documented, evaluated, and conserved throughout the world (Sarathbabu *et al.*, 1999). Based on the fruit shape, eggplant has been divided into three main types, namely, egg shaped (*S. melongena* var. *esculentum*), long slender shaped (*S. melongena* var. *serpentium*), and dwarf type (*S. melongena* var. *depressum*) (Kalloo, 1993).

Although the genus *Solanum* is predominantly central and South American, the eggplant is probably a native of Asia. De Candolle, in his "Origin of Cultivated Plants" published in 1886, states that the species *S. melongena* has been known in India from a very remote epoch. He further writes, "Thunberg does not mention it in Japan though several varieties are now cultivated in that country. The Greeks and Romans did not know the species, and no Botanist mentions it in Europe before the beginning of the 17th century, but its cultivation must have spread toward Africa before the middle ages". The Arab physician, Ebn Baithar, who wrote in the 13th century, speaks of it, and he quotes Rhasis who lived in the 9th century "A sign of antiquity in Northern Africa is the existence of a name, tabendjalts, among the Berbers or Kabyles of the province of Algiers." Hooker (1885), in his Flora of British India, states

as follows: "De Candolle says it is a native of Asia, not America, and Sendtner fixes its origin in Arabia: all this appears uncertain."

Vavilov (1951) mentions the occurrence of *S. melongena* L. in the Indian Center of origin of cultivated plants, which excludes Northwest India, Punjab and Northwest Frontier but includes Assam and Burma. He also mentions the occurrence of a special form of *S. melongena* with small fruits in the Chinese center of origin of cultivated plants. According to him the place of origin of *S. melongena* is the Indo-Burma region.

The cultivated eggplants have been shown to be susceptible to a variety of biotic and abiotic stress factors, which cause considerable loss of fruit yield and quality. The most common pests are Colorado potato beetle, shoot and fruit borer, *Epilachna* beetle, and stem borer. Among the diseases, fungal wilts caused by *Verticillium* spp. and *Fusarium oxysporum*, bacterial wilt caused by *Ralstonia solanacearum*, damping off caused by *Pythium* spp., *Phomopsis* blight caused by *Phomopsis vexans* and little leaf caused by mycoplasma are important. The abiotic stresses, particularly frost damage, drought, and salinity are important in eggplant. The conventional approaches have been used for the improvement of eggplant with special reference to fruit size, weight, and shape and resistance to diseases and pests (Kalloo, 1993), and in fact these have contributed for the development of several improved varieties of eggplant. There are also many wild species of eggplant that are resistant to pests and pathogens, and are important sources of agronomically important genes for its improvement (Collonnier *et al.*, 2001a; Kashyap *et al.*, 2003; Rajam and Kumar, 2006). Efforts to impart disease and pest resistance to the cultivated varieties have achieved limited success due to sexual incompatibilities with the wild relatives (Daunay and Lester, 1988; Kashyap *et al.*, 2003; Rajam and Kumar, 2006). However, the recent developments in eggplant biotechnology, including *in vitro* regeneration, protoplast culture and fusion, androgenesis and transgenics have facilitated the production of useful somatic hybrids and cybrids as well as transgenic plants with added values.

This chapter reviews the progress made in eggplant improvement using both conventional and nonconventional (biotechnological) techniques.

1.1 Traditional Strategies of Genetic Improvement in Eggplant

1.1.1 Interspecific hybridization

1.1.1.1 Traits of resistance in wild relatives

Eggplant is susceptible to numerous diseases and pests, particularly bacterial and fungal wilts, nematodes, and insects (Sihachakr *et al.*, 1994). The eggplant displays a great variability in morphological (color, shape, and size of plants, leaves and fruits), physiological, and biochemical characteristics. Moreover, resistance to most pathogens is also found in the cultivated eggplant, but its levels are partial and often insufficient for effective utilization in breeding programs (Messiaen, 1989; Daunay *et al.*, 1991). Resistance to bacterial wilt (*R. solanacearum*) (Li, 1988; Daunay *et al.*, 1991; Ali *et al.*, 1992b; Hanudin and Hanafiah Gaos, 1993) in some eggplant varieties has become ineffective during hot planting seasons or in poorly drained fields (Ano *et al.*, 1991). Only partial resistance against root-knot nematodes (*Meloidogyne* spp.), *Verticillium* (*V. dahliae*) and *Fusarium* (*F. oxysporum* f. sp. *melongena*) wilts, and to *Phomopsis* blight (*P. vexans*) is found in some varieties of eggplant (Yamakawa and Mochizuki, 1979; Messiaen, 1989; Ali *et al.*, 1992a). Likewise, some varieties have been reported to be only tolerant to insects, such as *Leucinodes orbonalis* (shoot and fruit borer), *Amrasca biguttula* (leaf hopper), *Aphis gossypii*, and *Epilachna vigintioctopunctata* (Bindra and Mahal, 1981; Chelliah and Srinivasan, 1983; Sambandam and Chelliah, 1983; Rotino *et al.*, 1997a). Therefore, it is greatly needed, through conventional breeding methods and biotechnological approaches, to introgress traits of high resistance to diseases and pests from eggplant landraces and wild relatives, displaying a great variability, into the cultivated eggplant. However, in Europe and some Asian countries like China and Japan, the release of F₁ hybrids, displaying higher productivity but with poor phenotypic variability has contributed to the losses of eggplant landraces, thus inevitably leading to the occurrence of genetic erosion of *S. melongena* (Daunay *et al.*, 1997). Moreover, some African cultivated eggplants also met genetic erosion following social, economic, and political changes (Lester *et al.*, 1990). Therefore, the cultivated

eggplants were considered priority species for the preservation of genetic resources since 1977, and several studies have been carried out in Asia and Africa (Lester *et al.*, 1990; Collonnier *et al.*, 2001a; Gousset *et al.*, 2005), and collections build up (Bettencourt and Konopka, 1990), particularly in China (Mao *et al.*, 2008).

Many wild relatives carrying traits of resistance to most diseases, pests, and environmental stresses affecting eggplant are summarized in Table 1. *Solanum sisymbirifolium* Lam. and *Solanum torvum* SW have been identified as resistant to the most serious diseases of eggplant, bacterial, and fungal wilts (Mochizuki and Yamakawa, 1979a, b; Messiaen, 1989; Daunay *et al.*, 1991). Resistance to *L. orbonalis* and to *Phomopsis* blight has been found in *Solanum khasianum* Clarke and *S. sisymbirifolium* Lam. (Kalda *et al.*, 1977). Interestingly, *Solanum aethiopicum* has been reported to be resistant to *L. orbonalis*, bacterial and *Fusarium* wilts (Ano *et al.*, 1991; Daunay *et al.*, 1991). Resistance to frost damage has been found in *Solanum grandiflorum* Ruiz and Pavon, *Solanum mammosum* L., and *S. khasianum* Clarke (Baksh and Iqbal, 1979), and tolerance to salinity in *Solanum linnaeanum* Hepper and Jaeger, and drought in *Solanum macrocarpon* L. (Daunay *et al.*, 1991) has been reported.

1.1.1.2 Sexual hybridization and its limitations

The use of conventional breeding methods has resulted in the improvement of agronomic and horticultural characteristics of eggplant, through mainly intraspecific crosses, and sporadically interspecific crosses because of sexual barriers between *S. melongena* and related wild species (Ano *et al.*, 1991; Bletsos *et al.*, 1998). The capability of eggplant to cross to species of other genera or subgenera is very low (Daunay *et al.*, 1991). This may result from the lack of genetic information about crossing partners, due to evolutionary divergence, which is known as incongruity (Franklin *et al.*, 1995). Attempt at crossing species from two species, *S. melongena* and *Solanum lycopersicum*, has resulted in sterile hybrids (Rao, 1979).

relatives is listed in Table 2. Among 19 species used throughout the world in attempts at crossing with *S. melongena* with a view to its genetic improvement, only four (*S. incanum* L., *S. linnaeanum* Hepper and Jaeger, *S. macrocarpon* L. and *S. aethiopicum* L.) have successfully resulted in developing partially fertile F₁ hybrids, giving rise to fertile progenies. The other 15 species, particularly *S. sisymbriifolium*, *S. torvum*, and *S.*

khasianum (Figure 1) with traits of resistance to the most serious diseases of eggplant, gave only partially fertile hybrids or no hybrids at all (Daunay and Lester, 1988). Some eggplant lines showed a variable ability to cross with a given wild species, and successful crosses may depend on one-way incompatibility (Rao, 1979). The low fertility of interspecific hybrids of *S. melongena* with other species of *Solanum* may be related to problems of

Figure 1 Flowers and fruits of *Solanum melongena* (a, e, i–l), *S. aethiopicum* Gilo group (b, f), *S. torvum* (c, g), *S. sisymbirifolium* (d, h)

self-incompatibility brought by the wild parent, and not by the eggplant being self-compatible (Daunay *et al.*, 1991). In the family Solanaceae, self-incompatibility was shown to be gametophytic and mainly controlled by a multiallelic *S*-locus (Franklin *et al.*, 1995).

In several interspecific crosses, *in vitro* embryo rescue was successfully used to recover sexual hybrids. Crosses between *S. melongena* and *S. khasianum* were successful through embryo rescue, but only when the wild species was selected as the female parent (Sharma *et al.*, 1980). Hybrid

plants were successfully obtained from crosses between eggplant and *S. sisymbirifolium*, when the latter was taken as the male parent and that the torpedo-staged embryos were excised and cultured. However, the resulted plants could not survive for very long time and died (Sharma *et al.*, 1984). In other studies, hybrids of *S. melongena* with *S. sisymbirifolium* and *S. torvum* have also been developed through embryo rescue (Daunay *et al.*, 1991; Bletsos *et al.*, 1998). In attempts at interspecific hybridization, the resulted hybrids have either been sterile or have had very low pollen fertility (Sharma *et al.*, 1980, 1984; McCammon and Honma, 1982; Bletsos *et al.*, 1998). Hybrid fertility can however be restored when the diploid hybrids ($2x$) were brought to the allotetraploid status ($2n = 4x = 48$ (AABB)) by application of colchicine, such as the sexual hybrids between eggplant and *S. macrocarpon* (Gowda *et al.*, 1990), *S. torvum* (Daunay *et al.*, 1991), and *S. aethiopicum* (Isshiki and Taura, 2003).

Although wild relatives are valuable and useful for genetic improvement of the cultivated eggplant through conventional breeding methods and biotechnology, the exploitation of such wild species in breeding programs must cautiously be undertaken. Some of them may carry undesirable traits, such as the very high susceptibility to *Colletotrichum gloeosporioides* found in *S. torvum*, and the bitter taste, due to a high level of steroid saponin in *S. linnaeanum* (Collonnier *et al.*, 2001a).

1.1.2 Anther culture

Spontaneous haploid induction has never been reported in eggplant. The first haploids in eggplant were obtained by the Research Group of Haploid Breeding (1978) in China and by Isouard *et al.* (1979), although previously Raina and Iyer (1973) reported plant regeneration from anther culture. The efficiency of the technique was greatly increased by Dumas De Vault and Chambonnet (1982) using a protocol similar to that applied to pepper (Dumas de Vault *et al.*, 1981), which is based on a high temperature (35 °C) treatment during the first period of anther culture. According to this method, excised anthers are cultured in the induction medium and placed in dark at 35 °C for the first 8 days of culture and then transferred to

growth chamber with normal dark/light cycles; on the 30th day, anthers are transferred to the differentiation medium. Embryos become visible from the anthers 1 month from the beginning of culture and the embryo production lasts for 3–4 months. Well-formed embryos easily form complete plantlets in a growth regulator-free medium. Minor modifications of this method have resulted in reliable protocols to produce androgenetic plants and enabled a successful incorporation of this technique in eggplant breeding programs to rapidly obtain homozygous lines and to release F_1 cultivar (Collonnier *et al.*, 2001a; Kashyap *et al.*, 2003). The most important factors influencing the yield of androgenetic plants are genotype, the environmental growth conditions of anther donors, culture media, and heat treatment of freshly cultured anthers (Rotino, 1996). Valuable genetic variation was displayed by doubled haploid lines obtained from anther donors represented by both inbred cultivar and highly heterozygous materials (Rotino *et al.*, 1991, 1992b). Plants were regenerated from isolated microspore culture following either anthers preculture (Gu, 1979) or direct culture of microspores (Miyoshi, 1996). *In vitro* androgenesis was successfully utilized to bring back the ploidy level to the diploid status of tetraploid interspecific hybrids between eggplant and the allied species *Solanum integrifolium* and *S. aethiopicum* gr *gilo*, and the “double somatic hybrid” obtained by sexual cross of the two somatic hybrids ((eggplant + *S. aethiopicum*) \times (eggplant + *S. integrifolium*)) (Rotino *et al.*, 2001, 2005; Kashyap, 2002; Rizza *et al.*, 2002). Dihaploids resistant to *F. oxysporum* f. sp. *melongenae* have been successfully backcrossed to eggplant and incorporated in the breeding program to develop new eggplant breeding lines with introgressed resistance to *Fusarium* wilt (Rotino *et al.*, 2001, 2005).

2. DEVELOPMENT OF TRANSGENIC EGGPLANTS

2.1 Regeneration *In Vitro*

The success of plant genetic engineering is determined by several factors, among which the availability of efficient plant regeneration from cultured cells/tissues is a crucial one. Eggplant

being a Solanaceae member is quite amenable for cell and tissue culture manipulations. Plant regeneration via organogenesis (both direct and indirect organogenesis) and somatic embryogenesis in cultivated as well as wild species of eggplants have been reported by a number of research groups, and such regeneration procedures have been successfully utilized in developing transgenic eggplants with new agronomic traits (Collonnier *et al.*, 2001a; Kashyap *et al.*, 2003; Kantarajah and Golegaonkar, 2004; Magioli and Mansur, 2005; Rajam and Kumar, 2006).

2.1.1 Organogenesis

Plant regeneration via organogenesis has been achieved by using a variety of explants including hypocotyl (Kamat and Rao, 1978; Matsuoka and Hinata, 1979; Alicchio *et al.*, 1982; Hinata, 1986; Sharma and Rajam, 1995a), epicotyl (Magioli *et al.*, 1998), stem nodes (Magioli *et al.*, 1998), leaf (Alicchio *et al.*, 1982; Gleddie *et al.*, 1983; Mukherjee *et al.*, 1991; Sharma and Rajam, 1995a; Magioli *et al.*, 1998), cotyledon (Alicchio *et al.*, 1982; Sharma and Rajam, 1995a; Magioli *et al.*, 1998), root (Franklin and Sita, 2003; Franklin *et al.*, 2004), cell suspensions (Fassuliotis *et al.*, 1981; Gleddie *et al.*, 1983), and protoplast cultures (Sihachakr and Ducreux, 1987a) in various cultivated eggplant varieties. It has been reported that hypocotyl explants are the best for organogenetic response followed by leaf and cotyledon explants (Sharma and Rajam, 1995a). It was also shown that regeneration response varied within single explant and followed a basipetal pattern, which was correlated with the spatial distribution of endogenous polyamines (Sharma and Rajam, 1995a, b). The number of shoots per explant reported by various groups is usually low (~7 shoots/explant), except the reports of Sharma and Rajam (1995a) and Magioli *et al.* (1998, 2000), where they could obtain about 20 shoots/explant. Scoccianti *et al.* (2000) have shown that organogenesis from cotyledon explant is correlated with the hormone-mediated enhancement of biosynthesis and conjugation of polyamines. In addition, several wild species of eggplant were also regenerated using different seedling explants (Rao and Narayanaswami, 1968; Kowlozyk *et al.*, 1983; Gleddie *et al.*,

1985; Kashyap, 2002) and cell (Fassuliotis, 1975) or protoplast cultures (Guri *et al.*, 1987).

In eggplant, shoot regeneration can be achieved by using cytokinins alone (Gleddie *et al.*, 1983; Mukherjee *et al.*, 1991; Sharma and Rajam, 1995a; Magioli *et al.*, 1998) or in combination with auxins. Direct shoot regeneration has been achieved by a combination of benzylaminopurine (BAP) and indole-3-acetic acid (IAA) (Sharma and Rajam, 1995a), kinetin (Mukherjee *et al.*, 1991), or thidiazuron (TDZ) (Magioli *et al.*, 1998, 2000). Indirect shoot regeneration was obtained by using combinations of IAA with BAP, kinetin, or zeatin (Kamat and Rao, 1978; Sharma and Rajam, 1995a), α -naphthalene acetic acid (NAA) and BAP (Matsuoka and Hinata, 1979) and combinations of IAA, 2,4-dichlorophenoxyacetic acid (2,4-D), and kinetin followed by IAA and 2-(isopentyl) adenine (2iP) (Fassuliotis *et al.*, 1981). Organogenic nodules developed in cell suspension culture using IAA and 2iP failed to develop to shoots until transferred to medium containing ascorbic acid or antiauxin *p*-chlorophenoxy isobutyric (PCIB) acid (Fassuliotis *et al.*, 1981).

It has been shown that a variety of factors such as the concentration and combination of phytohormones, genotype, explant source and age, and physical environment can influence the organogenetic response in eggplant (Collonnier *et al.*, 2001a; Kashyap *et al.*, 2003; Kantarajah and Golegaonkar, 2004; Magioli and Mansur, 2005; Rajam and Kumar, 2006). In most cases, the combination of BAP and IAA was found to be the best for shoot regeneration. Further, the ratio between BAP and IAA (the most optimum being 5:1) seems to be critical for better results (Sharma and Rajam, 1995a), which is also observed in other Solanaceae members, including tomato (Madhulatha *et al.*, 2006). However, low concentration of TDZ (100–200 nM) was useful in inducing efficient shoot regeneration (~20 shoots/explant) from leaf and cotyledon explants of five eggplant cultivars (Magioli *et al.*, 1998, 2000).

Tissue or cell cultures of eggplant has been used for the regeneration of plantlets on media supplemented with the pathogen toxins or abiotic stress agents in order to obtain potential lines resistant or tolerant to the above said conditions (Mitra *et al.*, 1981; Mitra and Gupta, 1989;

Sadanandam and Farooqui, 1991; Asao *et al.*, 1992; Ashfaq Farooqui *et al.*, 1997), or to understand gene function and activity (Alicchio *et al.*, 1984). Electrolyte release from regenerating eggplant calli has been used in screening for resistance and susceptibility to *V. dahliae* (Cristinzio *et al.*, 1994). Induction of laterals in root cultures of eggplant in hormone-free liquid medium was also reported and this system was used to demonstrate the role of polyamines in root growth and differentiation of lateral roots (Sharma and Rajam, 1997). They have shown that polyamines, particularly spermidine are intimately involved in root growth and differentiation of lateral roots.

2.1.2 Somatic embryogenesis

Somatic embryogenesis (SE) in eggplant has been very successful (Collonnier *et al.*, 2001a; Kashyap *et al.*, 2003; Kantarajah and Golegaonkar, 2004; Magioli and Mansur, 2005; Rajam and Kumar, 2006) (Figure 2). Auxins alone can induce SE in eggplant and cytokinins have been shown to be inhibitory (Matsuoka and Hinata, 1979; Gleddie *et al.*, 1983). The first induction of SE in eggplant by Yamada *et al.* (1967) was achieved using IAA. Later on NAA (Matsuoka and Hinata, 1979; Alicchio *et al.*, 1982; Gleddie *et al.*, 1983; Matsuoka, 1983; Fillipone and Lurquin, 1989; Rao and Singh, 1991; Mariani, 1992; Sharma and Rajam, 1995a, b; Fobert and Webb, 1988; Hitomi *et al.*, 1998) and 2,4-D (Ali *et al.*, 1991; Saito and Nishimura, 1994; Hitomi *et al.*, 1998) have been widely used. It was reported that 2,4-D could not induce SE in a Brazilian variety F-100, although SE was successfully induced with

NAA. Thus, NAA is very efficient in inducing somatic embryo differentiation. However, its optimal concentration varies with the explant and genotype. Leaf explants required 2–6 mg l⁻¹ of NAA for SE, while hypocotyls required 6–10 mg l⁻¹ (Matsuoka and Hinata, 1979; Gleddie *et al.*, 1983; Sharma and Rajam, 1995a). SE was also affected by nitrogen content with an optimum NO₃⁻/NH₄⁺ ratio of 2:1 and sucrose concentration (0.06 M) (Gleddie *et al.*, 1983). Culturing of seeds in the dark for preparation of seedling explants was found to be helpful in inducing SE (Ali *et al.*, 1991). The use of aseptic ventilative filter has been found to be helpful (Saito and Nishimura, 1994). The occurrence of both SE and shoot primordial has been observed in the same calli after prolonged culture in the presence of 21.6 µM NAA (Fari *et al.*, 1995a). The somatic embryos induced by NAA in eggplant are formed from perivascular parenchyma cells originating indeterminate meristematic masses, which can either give rise to adventitious shoots or proembryogenic masses (Tarre *et al.*, 2004).

The conversion of somatic embryos into plantlets is generally hampered due to the abnormalities like hyperhydricity, lack of apical meristem, fusion of cotyledons, and inefficient maturation (Gleddie *et al.*, 1983; Saito and Nishimura, 1994; Magioli *et al.*, 2001a). However, about 92% conversion rate has been reported by culturing mature embryos on Murashige and Skoog (MS) medium solidified with 1% phytoigel (Saito and Nishimura, 1994; Magioli *et al.*, 2001a).

The most important factor influencing SE in eggplant has been the genotype (Sharma and Rajam, 1995a, b). Genotype-dependant variations in physiology and metabolism in the explants have been decisive in induction of somatic

Figure 2 Somatic embryogenesis in eggplant from leaf tissue. (a) Formation of somatic embryos from callus, (b–d) scanning electron micrographs of various stages of somatic embryogenesis—globular, heart shaped, and torpedo somatic embryos

embryos (Sharma and Rajam, 1995a, b). It has been shown that the varietal difference exerted varied growth regulator requirement for optimum SE (Rao, 1992). It has also been validated through hybridization (Ali *et al.*, 1991) and gene expression (Afele *et al.*, 1996) experiments that the somatic embryogenic potential is genetically controlled.

Explant type also has been an important factor determining SE (Ali *et al.*, 1991; Sharma and Rajam, 1995a; Kantarajah and Golegaonkar, 2004). Various explants have been used in different protocols, which include leaves (Gleddie *et al.*, 1983; Rao and Singh, 1991; Sharma and Rajam, 1995a), cotyledons (Fobert and Webb, 1988; Saito and Nishimura, 1994; Sharma and Rajam, 1995a), and hypocotyls (Matsuoka, 1983; Ali *et al.*, 1991; Sharma and Rajam, 1995a). Leaves and cotyledons generally showed higher SE induction compared to hypocotyls (Sharma and Rajam, 1995a). Significant differences for morphogenetic potential were noticed within the different regions of a single explant—hypocotyl (Sharma and Rajam, 1995a, b) and leaf (Yadav and Rajam, 1997), which was attributed to the variation in the spatial distribution of polyamines.

In addition to plant hormones, very little is known about the additional means that may regulate plant morphogenesis *in vitro*. However, recent increasing evidences are showing the participation of polyamines in both SE and organogenesis and also other morphogenetic events from plant cells and tissues *in vitro* (Kumar *et al.*, 2006). Polyamines, which are considered to be the endogenous growth regulators, have been shown to be involved in the regulation of SE in diverse plant species, including eggplant (Kumar *et al.*, 2006). A thorough investigation has shown that the temporal changes in polyamines could be correlated with the variation in SE within the single explant (Sharma and Rajam, 1995a). It has also been demonstrated that the spatial distribution (Yadav and Rajam, 1997) and temporal regulation (Yadav and Rajam, 1998) of polyamines in explant correlates with SE process. Yadav and Rajam (1997) have demonstrated that the explants from different regions of the leaf showed significant variation in SE potential that was correlated with varying polyamine levels especially putrescine. It was also shown that the modulation of polyamine titers in the explants by exogenous addition has

resulted in the improvement of SE, suggesting the positive role of polyamines in the process. The follow-up study has further demonstrated the temporal regulation of SE by precise modulation of the endogenous polyamines during critical stages of SE (Yadav and Rajam, 1998). Data from these and other studies have been instrumental in establishing polyamines as biomarkers for plant regeneration (Shoeb *et al.*, 2001).

Studies on SE in eggplant have been extended recently to understand the molecular mechanisms underlying this important developmental process. A novel group of differentially expressing genes during SE has been identified through differential display (Momiyama *et al.*, 1995). An investigation into the molecular basis of difference among cultivars in SE using differential display has identified unique transcripts specific to the cultivar effectively producing SE in comparison to the one, which does not (Afele *et al.*, 1996). A more recent study has demonstrated the transcriptional expression of an *Arabidopsis thaliana* glycine-rich gene (*Atgrp-5*) during somatic embryo development in transgenic lines of eggplant carrying chimeric constructs using β -glucuronidase (GUS) fusion, where high promoter activity was detected in all cells of proembryogenic cell clusters and early stages in somatic embryo development (Magioli *et al.*, 2001a).

Somaclonal variations have also been reported in eggplant. For example, a salt-resistant line was obtained from cell culture in a medium fortified with 1% sodium chloride (Jain *et al.*, 1988). A somaclonal variant for resistance to little leaf disease was isolated from regenerants from tissue culture of infected plants (Magioli *et al.*, 1998). Synthetic seeds have also been developed by encapsulating somatic embryos with sodium alginate and calcium chloride (Rao and Singh, 1991; Mariani, 1992).

2.2 Protoplast Culture and Somatic Cell Hybridization

2.2.1 Protoplast culture

The control of plant regeneration from culture of organs, tissues, cells, and protoplasts is an essential prerequisite to the application of any techniques of biotechnology to supplement and

complement the conventional techniques aiming at genetic improvement in crops. In eggplant, plants could easily be regenerated through organogenesis and SE, using a variety of explant sources and this has been discussed in the previous section.

As far as the protoplast technology is concerned, plants of *S. melongena*, raised in growth chamber or greenhouse, gave poor yield of protoplasts, because of the presence of thick pubescence at the leaf surface, thus making sterilization difficult. Therefore, *in vitro*-grown plants have become the best source of protoplasts with good ability to high yield and develop, as they were sterilized, juvenile, and homogeneous (Saxena *et al.*, 1981; Sihachakr and Ducreux, 1987a). In most experiments, the primary choice of protoplast sources was concerned with the use of mesophyll tissues, from which high yield of protoplasts could easily be obtained. However, in some species, different steps of protoplast culture may encounter difficulties, needing the use of alternative protoplast sources. Protoplasts isolated from petioles were found to display a very high potential of development, compared to those from leaves and stems (Sihachakr and Ducreux, 1987a). A standard enzyme solution was effective for the isolation of protoplasts from various organs and tissues of eggplant and its wild relatives (Sihachakr and Ducreux, 1987a; Daunay *et al.*, 1993; Collonnier *et al.*, 2003a, b), potato (*Solanum tuberosum*) (Chaput *et al.*, 1990; Fock *et al.*, 2001), and sweet potato (*Ipomoea batatas*) (Sihachakr and Ducreux, 1987b; Sihachakr *et al.*, 1997).

The enzyme solution for eggplant protoplast isolation was composed of 0.5% (w/v) cellulase RS, 0.5% (w/v) macerozyme R-10 (Yakult, Tokyo, Japan), 0.5 M mannitol as osmotic agent and 0.05% (w/v) 2-(N-morpholino) ethane sulfonic acid (MES) buffer (Collonnier *et al.*, 2003a, b). The pH was adjusted to 5.5. About 500 mg of fresh plant material were incubated in 6 ml enzyme solution overnight in dark at 27 °C. The highest yield of eggplant protoplasts was obtained by using mesophyll as protoplast source with 9×10^6 protoplasts/g fresh weight, while petioles and stems gave 3.1 and 1.2×10^6 protoplasts/g fresh weight, respectively (Sihachakr and Ducreux, 1987a; Sihachakr *et al.*, 1993). Isolated protoplasts were highly heterogeneous. Most protoplasts from stems were highly vacuolated and floated on the surface of the culture medium, while those from

mesophyll and petioles, chlorophyllous and denser, dropped to the bottom.

Among numerous media routinely used, liquid basal and modified KM media (Kao and Michayluk, 1975) were found suitable for culture of eggplant protoplasts, particularly when supplemented with 0.2 mg/l 2,4-D, 0.5 mg l⁻¹ NAA, and 1 mg l⁻¹ BAP or zeatin (Sihachakr and Ducreux, 1987a; Collonnier *et al.*, 2003a, b). Glucose used at 0.35 M as osmoticum in the culture medium resulted in high viability and sustained cell division of eggplant protoplasts. Moreover, the addition of 250 mg l⁻¹ polyethylene glycol (PEG-MW 6000) to the culture medium enhanced the protoplast viability, probably due to its antioxidant property (Sihachakr *et al.*, 1993). In culture, protoplasts reformed the cell wall, and underwent cell division within 24 h and 3–4 days, respectively. However, after 7 days of culture, only 50% of cultured protoplasts survived, and some of them sustainably divided, giving rise to microcolonies. The frequency of cell division, observed after 10 days of culture, varied with the protoplast sources. The highest percentage of dividing cells was obtained with protoplasts from petioles, giving 33.4% division, followed by those from stems and lamina with 23.8 and 19.4% division, respectively (Sihachakr and Ducreux, 1987a). The division percentage was reduced to 10–15% by replacing the cytokinin zeatin with BAP in the initial culture medium. Moreover, cell growth was enhanced when diluting 10 times the cultures with fresh KM medium containing 0.1 mg/l 2,4-D and 2 mg l⁻¹ BAP or 0.2 mg l⁻¹ zeatin alone. The presence of zeatin in the diluting medium was shown to be favorable to further plant regeneration from cultured protoplasts of several species, particularly *Solanum nigrum* (Sihachakr and Ducreux, 1987c), *S. khasianum*, and *Solanum laciniatum* (Serraf *et al.*, 1988), and even sweet potato, which was known to be very recalcitrant (Sihachakr and Ducreux, 1987b; Sihachakr *et al.*, 1997). Three weeks after protoplast-derived calli were transferred onto the regeneration medium, containing 2 mg l⁻¹ zeatin and 0.1 mg l⁻¹ IAA, plant regeneration occurred by developing small deep-green spots. Sections of those spots showed embryo-like structures with two large cotyledons and a shoot meristem, but completely lacking the root. Some of them developed into leafy shoots, which can easily be rooted on

hormone-free medium. Interestingly, the callus ability to regenerate shoots was decreased and finally lost after maintaining the callus phase in 0.5 mg l^{-1} BAP and 0.5 mg l^{-1} NAA for more than 10 weeks (Sihachakr and Ducreux, 1987a). When transferred to the greenhouse, rooted shoots grew vigorously and showed similar morphology to the original plants. They intensely flowered and set fruits with viable seeds.

The successful development of the protoplast technology has provided the opportunity to apply biotechnology, such as somatic hybridization and genetic transformation, and gene transfer in view of improvement of eggplant (Collonnier *et al.*, 2001a; Kashyap *et al.*, 2003; Rajam and Kumar, 2006). Moreover, the cellular heterogeneity of the protoplast populations, as a single cell system, combined with an important callus phase during the culture, would result in regenerating somaclonal variants with interesting characteristics, which could further be selected and used in breeding programs. A salt-resistant line of eggplant was isolated from cell culture in a medium containing 1% sodium chloride (Jain *et al.*, 1988). In field trials, potential useful genetic variation for agronomic traits was observed in both embryogenic and androgenic eggplant lines (Rotino, 1996). In sweet potato, plants regenerated from cultured protoplasts showed a very great genetic variability, affecting plant morphology and physiology, particularly development and tuberization (Sihachakr *et al.*, 1997).

2.2.2 Somatic hybridization

The yield of cultivated varieties of eggplant is limited mainly by the susceptibility to diseases and pests, particularly bacterial and fungal wilts, which are the most serious diseases, causing heavy damages to this crop (Sihachakr *et al.*, 1994; Collonnier *et al.*, 2001b). Progress has been made to develop resistant lines by identifying and introgressing traits of disease resistance from wild relatives into cultivated eggplant through sexual crosses (Ano *et al.*, 1991; Bletsos *et al.*, 1998) and somatic hybridization (Sihachakr *et al.*, 1994; Collonnier *et al.*, 2001b; Kashyap *et al.*, 2003; Rajam and Kumar, 2006). Somatic hybridization by protoplast fusion offers the possibility of

overcoming sexual barriers or improving the fertility of hybrids obtained by conventional breeding methods (Daunay *et al.*, 1993; Sihachakr *et al.*, 1994). It provides the means of introgressing desirable agronomic traits without any detailed genetic and molecular knowledge of the genes encoding for such characters from wild into cultivated species (Jones, 1988; Collonnier *et al.*, 2001b). New and unique nucleo-cytoplasmic structures with a very high genetic variability are expected from the mixture of nuclear and cytoplasmic genomes of the fusion partners, occurring during somatic fusion.

The somatic hybridization through protoplast fusion between eggplant and its wild relatives is listed in Table 3. Protoplasts isolated from different sources, particularly leaves, cell suspensions, and calli were used in fusion experiments. Both electrical and chemical procedures, mainly the use of PEG, have successfully been applied for the production of somatic hybrids of eggplant with its wild relatives. In some fusion experiments, somatic hybrids were recovered by using selectable markers based on resistance to antibiotics, such as streptomycin and kanamycin, or chlorophyll-deficient mutant (Toki *et al.*, 1990; Guri *et al.*, 1991). In most experiments, the selection of eggplant hybrids was based on differences in the cultural behavior of hybrids and parental calli (Daunay *et al.*, 1993; Collonnier *et al.*, 2003a, b), and their identification was made upon the vigor and the morphological analysis of *in vitro*- and greenhouse-grown plants, particularly through the plant growth and morphology of leaves, inflorescence, flowers and fruits (Sihachakr *et al.*, 1994; Collonnier *et al.*, 2001b). The hybrid nature of selected plants was further confirmed by biochemical and molecular analysis, and chloroplasts of the parental and hybrid lines were identified by chloroplast DNA (ctDNA) restriction analysis (Daunay *et al.*, 1993; Collonnier *et al.*, 2003a, b). The ploidy level of somatic hybrids was determined by using flow cytometry and confirmed by chromosome count. Moreover, the composition of the hybrid genome was analyzed by using the technique of genomic *in situ* hybridization (GISH) (Collonnier *et al.*, 2003a, b).

The first successful somatic hybridization between cultivated eggplant and its wild species *S. sisymbriifolium* was conducted through PEG-mediated protoplast fusion, resulting in the

Table 3 Somatic hybridization in eggplant (*Solanum melongena* L.)

regeneration of 26 aneuploid hybrids. All the hybrids possessed only chloroplast genome of *S. sisymbirifolium*. They were highly resistant to root-knot nematodes and potentially resistant to spider mites, but further exploitation of those hybrids has been limited by strong hybrid sterility (Gleddie *et al.*, 1986). Similarly, four other tetraploid somatic hybrids were obtained by using electrofusion (Collonnier *et al.*, 2003a). They also had chloroplast genome of *S. sisymbirifolium*, and the analysis of the genome composition by using GISH technique clearly demonstrated the

presence of one complete set of chromosomes from both the parents in the hybrid nucleus. Moreover, *in vitro* tests revealed that the somatic hybrids were resistant to two bacterial strains of *R. solanacearum* and the filtrate of culture medium of *V. dahliae*. Since hybrid pollen was weakly fertile, the four somatic hybrids of eggplant with *S. sisymbirifolium* were expected to further be exploited in breeding programs (Collonnier *et al.*, 2003a). Electrofusion has successfully been used for production of 83 somatic hybrids between eggplant and *S. khasianum*, another useful wild

relative displaying resistance to shoot and fruit borer. A sample of six hybrid plants was examined for the chloroplast genome, and all had ctDNA type of eggplant (Sihachakr *et al.*, 1988). The hybrid plants grew vigorously in the greenhouse when grafted on eggplant rootstock because of difficulty in rooting. Despite 12% viable hybrid pollen, only parthenocarpic fruits without any seeds were obtained. Traits of resistance to the herbicide atrazine have been introgressed from *S. nigrum* into somatic hybrids of eggplant through chemical (Guri and Sink, 1988a) and electrical fusion procedures (Sihachakr *et al.*, 1989a). The hybrid plants had *S. nigrum* ctDNA, conferring resistance to 0.1 M atrazine. They developed abnormal morphology, affecting leaves and flowers, and produced only parthenocarpic fruits. The alteration of morphological traits was probably due to the aneuploid status of the hybrids with 90 chromosomes, close to the expected number (*S. melongena*: 24 + *S. nigrum*: 72 = 96) (Sihachakr *et al.*, 1989a). In somatic hybridization between eggplant and *S. torvum*, a very interesting wild relative with resistance to both bacterial and fungal wilts, chemical (Guri and Sink, 1988b) and electrical (Sihachakr *et al.*, 1989b; Collonnier *et al.*, 2003b) procedures have successfully been used, resulting in regeneration of 10 and 35 hybrid plants, respectively. Most of them had the eggplant ctDNA type, except one from electrofusion, displaying a mixture of chloroplasts from both the parents (Collonnier *et al.*, 2003b). The technique of GISH was applied to analyze the composition of the hybrid genome. As expected, the tetraploid hybrid plants contained one complete set of chromosomes from each fusion partner. On spread cytological preparation, the two parental genomes were not spatially separated at any time of the cell cycle. Translocation or recombinant chromosomes could not be demonstrated in the mitotic metaphase. The somatic hybrids were found resistant to nematodes and partially resistant to spider mite (Guri and Sink, 1988b). *In vitro* tests revealed that they had good levels of resistance to *R. solanacearum* and filtrate of culture medium of *V. dahliae*. Moreover, when grown to maturity in greenhouse, the hybrid plants flowered, but the pollen viability was reduced (Collonnier *et al.*, 2003b).

Somatic hybridization between eggplant and *S. aethiopicum* has provided a good example of

successful exploitation of somatic hybrids in breeding programs. Electrofusion was used to produce somatic hybrid plants aiming at introgressing traits of resistance to bacterial and fungal wilts from *S. aethiopicum* into cultivated eggplant (Daunay *et al.*, 1993; Rotino *et al.*, 2001) (Figure 3). Most of the hybrids had the eggplant ctDNA type. Field evaluation showed that the somatic hybrids had better pollen viability, estimated at 30–85%, compared to sexual counterparts with only 20–50%. Some somatic hybrid clones gave a very good yield of fruits up to 9 kg/plant, which was three to four-times as high as that of the parental lines, while the sexual hybrids produced only very few fruits. Tests carried out in a contaminated field in Bogor (Indonesia) revealed that the somatic hybrids were highly resistant to bacterial wilt. Similarly, other fertile somatic hybrids of eggplant with *S. aethiopicum* were shown to also be resistant to *Fusarium* wilt (Rotino *et al.*, 1998, 2001). The fertile tetraploid somatic hybrids have successfully been brought back to diploid status through anther culture (Rizza *et al.*, 2002), and the resulted dihaploid hybrids have been backcrossed to the recurrent eggplant (Rotino *et al.*, 2005). Interestingly, analysis of morphological traits and molecular markers, particularly isozymes and ISSRs (inter-simple sequence repeats), strongly suggested that genetic reassortment/recombination between the genomes of *S. melongena* and *S. aethiopicum* occurred during meiosis and it was expressed in the dihaploid somatic hybrid plants. Moreover, fertility and morphology close to cultivated eggplant were progressively recovered after a series of backcrosses of the dihaploids to cultivated eggplant. Thus, the resulted backcrossed progenies with fungal resistance can easily be incorporated in breeding programs of eggplant (Rotino *et al.*, 2005).

Protoplast fusion was also used to produce intergeneric hybrids of *S. melongena* with a triple mutant, chlorophyll-deficient, streptomycin and kanamycin-resistant *Nicotiana tabacum*, on which was based the selection scheme to recover the hybrids (Toki *et al.*, 1990). Interestingly, somatic hybridization between eggplant and a sexual hybrid of tomato with its wild relative, *Lycopersicon pennellii*, has been performed, resulting in the formation of only hybrid calli with few leaf primordial at first (Guri *et al.*, 1991), and then normal plants were regenerated after

Figure 3 Variability in the shape, size, and color of fruits produced by dihaploid plants derived from anther culture of somatic hybrids between eggplant and *S. aethiopicum*

irradiating one fusion partner with γ -rays (Liu *et al.*, 1995; Samoylov and Sink, 1996; Samoylov *et al.*, 1996).

Although the combination of complete genomes can easily be obtained through somatic fusion, the resulted somatic hybrids, particularly between distant parents, are often sterile, thus limiting their further exploitation in breeding programs (Sihachakr *et al.*, 1994). An additional difficulty is their amphiploid status, and it is needed to bring tetraploid hybrids back to the diploid status, which is more suitable for intensive backcrosses to the diploid recurrent eggplant for introgression of desirable traits. Moreover, when the fusion partners are distantly related, the final product is often an asymmetric combination of the two genomes (Gleba *et al.*, 1984; Pelletier *et al.*, 1985; Pijnacker *et al.*, 1989). Therefore, a potential approach could be the production of highly asymmetric somatic hybrids bearing

few chromosome fragments from one parent associated with a complete set of chromosomes from the other parent (Jones, 1988; Sihachakr *et al.*, 1994). Interestingly, fertile somatic hybrids with tolerance to *Verticillium* wilt and morphology close to the cultivated eggplant have successfully been obtained after fusion between eggplant protoplasts and x-rays irradiated protoplasts of *S. torvum* (Jarl *et al.*, 1999). Furthermore, as plant regeneration is difficult from fusion between remote species, it would be of great interest to increase cytoplasmic variability in eggplant through organelle transfer via asymmetric fusion of protoplasts.

In conclusion, through several successful examples of somatic hybridization in eggplant, it is needed to include the technique of protoplast fusion in breeding programs of eggplant to complement and supplement the conventional breeding techniques for genetic improvement of

this crop. The somatic fusion provides the means for a rapid introgression of useful traits without any detailed knowledge of the genes encoding for the traits from wild into cultivated species.

2.3 Genetic Transformation

The most important prerequisite for genetic manipulation of a plant species is the availability of a standard procedure for the introduction of foreign genes. Members of the family Solanaceae are highly amenable for tissue culture and genetic transformation. Several groups achieved genetic transformation of a number of eggplant varieties via *Agrobacterium* during the last two decades (Table 4). The production of transgenic plants was first reported by Guri and Sink (1988c), using leaf explants and the cointegrate vector pMON 200 carrying the *nptII* gene. In the following year, Fillipone and Lurquin (1989) reported stable transformation of leaf and cotyledon explants using a binary vector. Since then, transgenic eggplants have been obtained using several *Agrobacterium* strains harboring binary vectors carrying *nptII* gene as a selection marker and different reporter genes, including *gus*, *cat* (chloramphenicol acetyl transferase) and *luc* (luciferase).

Transformation efficiency of eggplant is mainly influenced by preconditioning of the explants, regeneration pathway, antibiotics used to eliminate bacteria, bacterial density, and the explant type. Therefore, these factors should be evaluated for different genotypes in order to establish a successful protocol.

Preconditioning of explants before co-cultivation with *Agrobacterium* by culture in regeneration inducing medium has been reported for several species and is a determining factor to produce or improve the production of transgenic eggplant. The use of a preculture period of 48 h on solid medium has been adopted both for cotyledon and leaf explants (Rotino and Gledie, 1990; Arpaia *et al.*, 1997; Iannacone *et al.*, 1997). Fari *et al.* (1995b) demonstrated that a preculture of cotyledon explants for a period of 48 h followed by a 48 h co-culture in liquid regeneration medium period significantly improved the recovery of transformants. No kanamycin-resistant tissues were formed following 24 h co-culture and

transformation efficiency decreased by half when the preculture was not adopted. Magioli *et al.* (2000) also showed that a 48 h preculture of cotyledon explants in solid or 24 h in liquid regeneration medium (MS + 200 nM TDZ) resulted in a significant increase in the frequency of kanamycin-resistant calli formation and shoot production. More recently, a preculture period of 48 h on MS medium supplemented with 2 mg l⁻¹ kinetin or 2.5 mg l⁻¹ BAP + 0.5 mg l⁻¹ IAA was found to be optimum to ensure transformation from leaf explants (Kumar and Rajam, 2005).

The production of transgenic eggplant through SE either fails to occur (Fillipone and Lurquin, 1989) or is achieved with very low efficiency (Fari *et al.*, 1995b) when using cefotaxime as the bactericidal antibiotics. Both co-cultivation with *Agrobacterium* and the presence of bactericidal antibiotics used in transformation protocols cause a reduction of up to 80–99% in the number of embryos/explant (Magioli *et al.*, 2001b). The inhibitory effect on somatic embryos development may result from the interaction between the physiological alterations caused by these treatments and the delicate processes of gene regulation that are induced in early culture stages. Antibiotics used to eliminate *A. tumefaciens* can also influence the efficiency of transformation protocols based on organogenesis. For example, augmentin can cause enhanced shoot regeneration induced by TDZ (Billings *et al.*, 1997).

Bacterial culture densities in the range of A₆₀₀ = 0.2–0.6 usually result in high transformation rates. Although higher number of GUS-expressing foci in transformed explants can be achieved with higher densities, the regeneration potential is greatly reduced, resulting in the production of low number of transgenic shoots (Kumar and Rajam, 2005).

The great majority of transformation protocols of eggplant is based on the use of leaf, cotyledons, and hypocotyl explants of *in vitro*-grown seedlings and generally cotyledons show the highest transformation efficiency. For example, the use of leaf segments resulted in two times lower transformation efficiency as compared to cotyledons (Fari *et al.*, 1995b; Magioli *et al.*, 2000). Interestingly, recent experiments using *Agrobacterium tumefaciens* strain A348 (pSM358) harboring a *VirE::lacZ* fusion construct, which carries hygromycin phosphotransferase gene (*hpt*) as

a selection marker and a green fluorescent protein (*gfp*):*gus* fusion gene as a reporter, demonstrated that leaf, cotyledon, and hypocotyl explants are poor inducers of *vir* genes. Modulation of *vir* genes induction by adding 100 μ M acetosyringone during infection and co-cultivation steps resulted in a twofold to threefold increase in transformation frequency. It has also been demonstrated that although hypocotyls explants are superior to leaf and cotyledon explants regarding the percentage of explants showing transient GUS expression, the latter two are significantly more efficient in regenerating transformed shoots (Kumar and Rajam, 2005).

A high transformation efficiency was achieved with an organogenic system from root explants and *A. tumefaciens* strain LBA4404 harboring the binary vector pBAL2 with the reporter gene *gus* containing an intron (GUS-INT) and the marker gene *nptII*. Transgenic calli of the variety MEBH 11 were obtained on medium supplemented with 0.1 mg l^{-1} TDZ and 3.0 mg l^{-1} N-6-benzylaminopurine. Root explants demonstrated a high susceptibility to *Agrobacterium* and quick regeneration capacity on selection media containing 100 mg l^{-1} kanamycin and 500 mg l^{-1} cefotaxime, resulting in 82.5% of transgenic calli induction with a means of 24 transgenic shoots per callus (Franklin and Sita, 2003).

Protocols based on the use of leaf, cotyledon and hypocotyl explants were successfully used to introduce agronomic traits into eggplant (Table 4). Resistance to Colorado potato beetle (*Leptinotarsa decemlineata* Say) (CPB), a pest that has developed resistance to synthetic insecticides and became a serious problem for agriculture in Europe and America (Arpaia *et al.*, 1997), has been pursued by a number of groups. Chen *et al.* (1995) have produced transgenic eggplant lines with the introduction of *Bacillus thuringiensis* (*Bt*) genes, but resistance to CPB was not observed. Later, different groups obtained lines resistant to CPB by using mutagenized versions of *cryIIIB* (Rotino *et al.*, 1992a; Arpaia *et al.*, 1997; Iannacone *et al.*, 1997) and a synthetic version of *cryIIIA* (Jelenkovic *et al.*, 1998) *Bt* genes. Field trials demonstrated high levels of resistance in transgenic plants produced after the introduction of a mutagenized *Bt cryIIIB* gene, without detrimental effects on nontarget arthropods (Rotino *et al.*, 1992a; Acciarri *et al.*, 2000; Mennella *et al.*, 2005).

Resistance to *L. orbonalis*, a lepidopteran insect that causes extensive damages to fruits and shoots, was obtained in transgenic plants produced through transformation of cotyledon explants with the strain EHA105 harboring a synthetic *cryIAb* gene modified for rice codon usage and carrying a castorbean catalase intron (Kumar *et al.*, 1998). Eggplant lines expressing *Bt-cryIFal* gene were recently developed and tested to be more effective than *cryIAb*-expressing lines (Kumar, unpublished). Efforts to commercialize eggplant hybrids expressing CryIAc protein are currently underway in India.

Recently, a gene encoding oryzacystatin was introduced in eggplant and the effect on *Myzus persicae* and *Macrosiphum euphorbiae* was examined (Ribeiro *et al.*, 2006). The transgenic eggplant reduced the net reproductive rate, the instantaneous rate of population increase, and the finite rate of population increase of both aphid species compared with a control eggplant line. Age-specific mortality rates of *M. persicae* and *M. euphorbiae* were higher on transgenic plants. These results indicate that expression of oryzacystatin in eggplant has a negative impact on population growth and mortality rates of *M. persicae* and *M. euphorbiae* and could be a source of plant resistance for pest management of these aphids. Expression of *Mi-1* gene isolated from tomato in eggplant cv. HP 83 conferred resistance to root knot nematode *Meloidogyne incognita* (Goggin *et al.*, 2006).

Attempts have also been made to engineer eggplant for fungal resistance. Overexpression of an yeast Δ -9 desaturase gene in eggplant has resulted in higher concentrations of 16:1, 18:1, and 16:3 fatty acids, and such transgenics exhibited increased resistance to *Verticillium* wilt (Xing and Chin, 2000). Transgenic plants challenged by *Verticillium* could also result in a marked increase in the content of 16:1 and 16:3 fatty acids. They have shown that *cis*- Δ 9 16:1 fatty acid was inhibitory to *Verticillium* growth. Transgenic eggplants resistant to *Verticillium* and *Fusarium* wilts by overexpression of pathogenesis-related genes, such as glucanase, chitinase and thaumatin (singly and in combination) were also produced (Singh, 2004).

Tolerance against osmotic stress induced by salt, drought and chilling stress was achieved in eggplants expressing the bacterial mannitol-1-phosphodehydrogenase (*mtlD*) gene, which is

involved in the mannitol synthesis (Prabhavathi *et al.*, 2002). Interestingly, these transgenic plants also showed enhanced resistance to fungal wilts caused by *V. dahliae* and *F. oxysporum*. Further, various transgenic eggplants overexpressing different genes (namely, arginine decarboxylase, ornithine decarboxylase, S-adenosylmethionine decarboxylase, and spermidine synthase) encoding enzymes in the polyamine metabolic pathway have also been generated. These transgenic plants showed increased tolerance to multiple abiotic (salinity, drought, extreme temperature, and heavy metals) as well as biotic (fungal pathogens) stresses. A gene pyramiding approach is also being pursued, in which the genes responsible for various agronomical important traits, including abiotic stress tolerance and fungal disease resistance, are being introduced in combination into eggplant through co-transformation.

Transgenic eggplants with parthenocarpic fruits were also developed by manipulating the auxin levels during fruit development through the introduction of *iaaM* gene from *Pseudomonas syringae* pv. *savastanoi* under the control of the ovule-specific promoter DefH9 from *Antirrhinum majus* (Rotino *et al.*, 1997b). These transgenics produced seedless parthenocarpic fruit in the absence of pollination without the external application of plant hormones, even at low temperature, which normally prohibit fruit production in untransformed lines. Further, these transgenics have exhibited significantly higher winter yields than the untransformed plants and a commercial hybrid under an unheated glasshouse trial (Donzella *et al.*, 2000). Trials in open field for summer production and greenhouse for early spring production confirmed that transgenic parthenocarpic eggplant F₁ hybrids gave a higher production coupled with an improved fruit quality with respect to the untransformed controls (Acciarri *et al.*, 2002). Quality parameters of frozen parthenocarpic fruits did not show any significant changes when compared to their controls (Maestrelli *et al.*, 2003).

3. CONCLUSIONS

Extensive studies have been performed on eggplant regeneration via both organogenesis and SE using tissues, cells, and protoplasts. Efficient regeneration systems have been achieved in a wide

variety of genotypes. Such regeneration protocols were successfully utilized to develop protocols for genetic transformation of eggplant, particularly via *Agrobacterium* and also somatic hybridization through protoplast fusion. Significant progress has been made in genetic improvement of eggplant through the use of conventional as well as biotechnological tools such as androgenesis, somatic hybridization, and genetic transformation. The studies on molecular markers like random amplified polymorphic DNA (RAPD), restriction fragment length polymorphism (RFLP), and amplified fragment length polymorphism (AFLP) have not been exploited fully in eggplant breeding, and considerable attention is needed for developing comparative phylogenetic maps and molecular markers for pest and disease resistance as well as for various other useful traits. The genetic engineering approach seems to be very promising for the improvement of eggplant as transgenic lines with interesting traits, particularly resistance or tolerance to insects, nematodes, diseases, and abiotic stress, as well as parthenocarpic fruits have successfully been developed. Value addition to eggplant in terms of vitamins and iron will help ameliorate problems of malnutrition and under nourishment in many Asian countries. Tomato genome sequencing is currently underway as part of the larger initiative "International Solanaceae Genome Project" (SOL) (Mueller *et al.*, 2005). This sequencing project would offer exciting new perspectives and opportunities for eggplant improvement as the key genes that are responsible for various agronomically important traits, including plant architecture, disease and pest resistance, and fruit yield and quality would soon be available. A high degree of sequence similarity among the genomes of Solanaceae members facilitates cross utilization of microarray (genomics) tools and resources and will impact the improvement of all the cultivated members. An intensive effort to dissect the functional aspects of eggplant genome will hasten our efforts to improve the crop.

1. INTRODUCTION

The genus *Capsicum* is one of the most important members of Solanaceae crops that include tomato, potato, eggplant, tobacco, petunia, and others. Almost five billion people in the world utilize peppers not only for food and spices but also for colorants and medicines. Peppers are cultivated in six continents ranking seventh in the harvested area under vegetable crops in the world and the classical breeding program for pepper cultivation has been well established in Asia and Europe with increasing number of elite F₁ hybrid varieties. Traditional pepper breeding has been focusing on traits such as yield, environment adaptation, fruit color and shape, and disease resistance. However, limited genetic resources for breeding and increasing demand for better pepper varieties require new tools for pepper breeding.

Two most important biotechnological tools for crop improvement are plant transformation and molecular marker-assisted breeding. For the last 10 years, farmers have constantly increased their cultivation area under genetically modified (GM) crops every year since GM crops were first commercialized in 1996. However, no GM pepper varieties have been commercialized; no GM peppers have been under field test due to the difficulties in transformation of peppers. One of the most important steps in plant transformation

is plant regeneration (Valera-Montero and Ochoa-Alejo, 1992; Ebida and Hu-C 1993; Harini and Sita, 1993). Despite continuous efforts, successful reports of pepper transformation are very limited. Even among the successful groups in pepper transformation, the transformation efficiencies have been very low and the transformation was neither consistent nor reproducible. Therefore, commercial GM varieties in peppers are still a long way to go. In this review, we will present a general overview of the genus *Capsicum* and current status of pepper transformation. In addition, we will introduce one of the successful protocols for pepper transformation at the end of this review.

1.1 History, Origin, and Distribution

The origin of *Capsicum* species, commonly known as peppers, is believed to be in South America, either central Bolivia along Río Grande (Andrews, 1995) or Brazil along the Amazon (DeWitt and Bosland, 1993). These areas concentrated with large wild species of peppers are also known as the nuclear areas (DeWitt and Bosland, 1993; Andrews, 1995). There are at least two centers of domestication, one in central America and the other in the Andean region of South America. Five species, among approximately 30 in the genus, were independently domesticated and have been

cultivated primarily for use as spice and vegetable for thousands of years (Andrews, 1995). Columbus introduced *Capsicum* into Europe in the 15th century, subsequently it was distributed rapidly around the world. Following its arrival in western Europe, both pungent and nonpungent forms of the species *C. annuum* came into wide cultivation, assuming a particularly important role in the cuisines of some parts of Europe, e.g., Hungary, West Africa, and many regions of Asia.

In western Europe and North America, relatively large, nonpungent bell type (*C. annuum*) became dominant in the 18th and early 19th century (Boswell, 1937). The pungent types remain favored in Latin America, Asia, and Africa. Today *Capsicum* is grown in tropical, subtropical, and temperate regions worldwide and *Capsicum* varieties are utilized for a diverse range of food products as vegetable and spice, fresh, dehydrated or processed, in medicine, in pest and animal control, and even in law enforcement, which make this crop of immense cultural and economic importance (Bosland and Votava, 2000).

1.2 Botanical Features

1.2.1 Taxonomy

The genus *Capsicum* belongs to the tribe Solanae, a family member of the Solanaceae (Hunziker, 2001). *Capsicum* is closely related to *Solanum*, to which two other important vegetable crops, tomato (*S. lycopersicum*) and potato (*S. tuberosum*), belong (Olmstead *et al.*, 1999; Martins and Barkman, 2005). About 30 species are currently recognized under the genus of *Capsicum* (Baral and Bosland, 2002), although the actual number of species is still debatable. In fact, taxonomy of the genus of *Capsicum* has long been confusing and arguable. Botanists traditionally define nomenclature and classification of *Capsicum* species based on morphological and anatomical characteristics. Phylogenetic relationship can also be determined by investigating hybridization performance between the *Capsicum* species (Tong and Bosland, 1999). Recently, molecular phylogenetic study has been carried out with 11 species of *Capsicum* with the aim of clarifying the phylogenetic ambiguity related to *Capsicum* (Walsh and Hoot, 2001).

C. annuum, *C. chinense*, and *C. frutescens* are the three main cultivated *Capsicum* species in agriculture worldwide. Types of cultivated *C. annuum* include bell pepper, jalapeño, New Mexico chile, ancho, Anaheim, and banana pepper, to name just a few. Many local varieties and landraces are also grown widely mostly in Latin America. In addition to these three species, two other domesticated species, *C. pubescens* and *C. baccatum*, are grown primarily in Latin America. *C. pubescens* has distinctive purple flowers and black seeds and was domesticated in the Peruvian and Bolivian Andes. Wild forms of all domesticated species have been identified, except of *C. pubescens* (Pickersgill, 1997).

1.2.2 Germplasm

Germplasm collection is extremely important in pepper breeding. Diversity of genetic resources is utilized for bringing new traits, particularly for resistance to new diseases and alternative resistance sources for existing diseases. Besides crop improvements, germplasm also plays an important role in various scientific researches, such as elucidation of evolution and classification of *Capsicum* species, understanding biology and biochemistry in peppers. Agricultural Research Service of United States Department of Agriculture (USDA-ARS) in Griffin (Georgia, USA) and Asian Vegetable Research and Development Center (AVRDC), the world's vegetable center based in Taiwan, have the world's largest collections of *Capsicum* germplasm and are active in characterization, evaluation and conservation. AVRDC has a total of 7726 accessions of *Capsicum* spp. as of September 2006 (<http://www.avrdc.org>); USDA-ARS has more than 4700 accessions of 16 *Capsicum* taxa in its active collection program in Griffin (Stoner, 2004). These two organizations also maintain databases for their collections and distribute seeds to pepper researchers and breeders all over the world. Other institutions, universities, government or nongovernment organizations, and private seed companies have various scales of *Capsicum* germplasm collections (Berke and Engle, 1997). Germplasm of *Capsicum* of at least 15 countries have been reported in *Capsicum and Eggplant Newsletter* (CENL) in the past 20 years (1983–2002).

1.2.3 Habitat and morphology

Wild *Capsicum* plants are perennial shrubs; commercial pepper cultivars are usually grown as annual crops. As a perennial, the plant turns from herbaceous to woody with age. *Capsicum* species has perfect and complete flowers. As a member of Solanaceae, flowers of *Capsicum* typically have five sepals, petals, stamens, and pistil. Color of petals (or corolla), stamens, and pistil can be white, greenish white, greenish yellow, or purple, combination varies depending on species and varieties. Cultivated *Capsicum* species are primarily self-pollinated and do not display inbreeding depression. Peppers can also be cross-pollinated by insects, outcrossing rate varies depending on the cultivars. Temperature, particularly night-time temperature is critical for fruit set (Andrews, 1995). The optimal day temperature for fruit setting of cultivated pepper is between 20–30 °C in chili pepper and 21–24 °C in sweet pepper, but fruits fail or have difficulty to set when night temperature exceeds 24 °C; growth of the plants is also reduced when air temperature is less than 15 °C or more than 32 °C for chili pepper and less than 18 °C or more than 27 °C for sweet pepper (<http://www.avrdc.org>).

Pepper fruit is the commodity of the pepper plant; therefore, fruit morphology, flavor, and pungency are the most economically important characteristics in *Capsicum*. A tremendous amount of genetic variation is known with respect to fruit traits such as size, shape, color, and flavor, resulting in more than 50 commercially recognized pod types. Bosland (1992) and Andrews (1995) described the major fruit types.

1.2.4 Genome size, karyotype, and ploidy level

The genome size of pepper was estimated to be 7.65 pg/nucleus for *C. annuum* and 9.72 pg/nucleus for *C. pubescens* (Belletti *et al.*, 1998). Genome size in nucleotides is estimated to be about 3000 Mbp (mega base pairs) (Arumuganathan and Earle, 1991). Most *Capsicum* species has 12 pairs of chromosomes; however, *C. ciliatum* has 13 pairs of chromosomes. Polyploidy is very rarely observed in *Capsicum* (Lippert *et al.*, 1966). The development of doubled haploid (DH) lines by

anther culture is common to obtain homozygous genotypes of interest and to develop populations for inheritance studies and the construction of genetic maps (Pochard *et al.*, 1983a; Lefebvre *et al.*, 1995). A set of trisomic lines were produced by Pochard (1977) and used for the chromosomal assignment of several mutations. Various types of chromosomal rearrangements are prevalent in the genus both within and between species (Pochard, 1977; Onus and Pickersgill, 2004).

1.3 Economic Importance and Consumption of Pepper

Peppers are the third-most important vegetable crops worldwide, grown in most countries in the world with production more than 22 million tons annually (FAO, 2002). The world's largest producer of peppers is China (more than 8 million tons in 2001) followed by Mexico and Turkey, which produced 1 900 000 and 1 400 000 tons, respectively in 2001. Spain, Italy, and the Netherlands are the main growers in Europe. Peppers are important source of income for farmers in most parts of the world.

Consumption of pepper is closely associated with cultures and diets. People in different countries or different regions of a country have different demands for fruit type, color, shape, maturity, taste, and pungency of peppers. For fresh- and dried-vegetable market, *C. annuum* is the dominated species of cultivated *Capsicum*, although *C. chinense* and *C. frutescens* are also commonly grown in some regions (Andrews, 1995). *C. pubescens* and *C. baccatum* have minor market in Latin American culture. Pepper fruit is mainly used as fresh and dried vegetable; leaf of pepper plants is also consumed as leafy vegetable in some cultures. Fresh and dried vegetable peppers can also be used in making sauces; the famous “Salsa” sauce is made with serrano and jalapaños (Andrews, 1995).

Peppers are also important crops for processed food industry. Three species of *Capsicum* are used for processed pepper: *C. annuum*, *C. chinense*, and *C. frutescens*. The major uses of peppers in processing industries are pickle, sauce and powder. Thompson (1995) collected and described more than 350 hot sauces from all over the world, including the best-known pepper sauce,

Tabasco (*C. frutescens*). Pepper fruits are dried or dehydrated and processed to produce pepper powder, also known as paprika in Europe. Pepper powder is an important spice particularly in Hungary and India.

In addition to its importance as a food and spice, peppers have been used and continue to be used widely for diverse medicinal applications (Bosland and Votava, 2000). Because capsaicinoids interact specifically with the mammalian pain receptor, VR1, they have been widely used as topical analgesics (Caterina *et al.*, 2000). While pain control is the most familiar application, hundreds of publications each year report various pharmacological applications of these molecules from weight loss to cancer.

1.4 Chemical Composition and Nutrition

1.4.1 Capsaicinoids

Capsicum may be best known for its biosynthesis of capsaicinoids that account for the pungent or “hot” sensation when consumed. Capsaicinoids have only been found in *Capsicum* species, but not all *Capsicum* species are pungent, for instance, nonpungent form can be found in *C. annuum*, *C. ciliatum*, and *C. chacoense*. Capsaicinoids are thought to play an important role in the evolution of *Capsicum* species. Tewksbury *et al.* (2006) studied the geographic variation of pungency within three species of ancestral *Capsicum* in Bolivia and found that production of capsaicinoids shifts across elevations. It was suggested that capsaicinoids entails both costs and benefits in response to selection pressure (Tewksbury *et al.*, 2006). It has been hypothesized that this trait evolved to deter mammalian herbivory, where crushing molars and acidic digestion are detrimental to seed survival (seed predator). The favored agents of dispersal are various species of birds. Avian species do not perceive pain in response to capsaicin and are attracted by the brightly colored fruit of *Capsicum* (Tewksbury and Nabhan, 2001).

Capsaicinoids include a family of up to 25 related alkaloid analogs produced in epidermal cells of the placenta or dissepiments of the fruit. The two major capsaicinoid compounds are capsaicin and dihydrocapsaicin. The gene *AT3*

(acyltransferase 3) at *Pun1* locus was identified for the biosynthesis of capsaicin (Stewart *et al.*, 2005). Nevertheless, the genetic base of biosynthesis of other quantitatively inherited capsaicinoids is still poorly known (Blum *et al.*, 2003). Biosynthesis of capsaicinoids is complicated and accumulation of capsaicinoids varies dramatically within and between *Capsicum* species. A number of analytical techniques have been reported for the determination of pungency in pepper and summarized by Pruthi (2003). Scoville index and high-performance liquid chromatography analysis represent the two generations of the most widely used techniques in pungency measurement (DeWitt, 1999); spectrophotometric method is used as ISO Reference method (Pruthi, 2003).

1.4.2 Pigments and vitamins

The most common colors of pepper fruits are green, red, yellow and orange, and chocolate or purple. Green peppers are usually not mature; the mature color ranges from lemon or yellow through orange, peach, and red. Growing and storage conditions alter color of pepper fruits (Gómez *et al.*, 2003). Pepper color is associated with its pigment content. Carotenoid and anthocyanin pigments are responsible for fruit color and for nutritional value of *Capsicum* fruit. Red color is resulted from the accumulation of different carotenoids in fruit chromoplasts during fruit ripening. The predominant red pigments are capsanthin and capsorubin, the yellow and orange pigments are lutein, β -carotene (provitamin A), zeaxanthin, violaxanthin, and antheraxanthin (Buckenhüskes, 2003). Carotenoid biosynthetic pathway in pepper fruit and putative correspondences with quantitative and qualitative organ-color loci identified in the Solanaceae was proposed by Thorup *et al.* (2000).

Peppers are well known as nutritious crop with very low calories, particularly rich in vitamin A and C. Peppers are ranked first in antioxidant content among vegetables with very high levels of vitamin C (Palevitch and Craker, 1995). Consumption of a single pepper fruit is enough to meet an adult Recommended Dietary Allowances for this vitamin. A list of nutrients of different peppers is provided at www.chilepepperinstitute.org. Vitamin C concentration is high in green fresh fruits, but is

lower in mature fruits and it breakdowns in dried or dehydrated pepper products. As for vitamin A, its accumulation increases as fruits turn matured to red or orange. Unlike vitamin C, high level of vitamin A is retained in dried fruits (DeWitt, 1999).

1.5 Breeding Objectives

1.5.1 Breeding for yield

Yield, like all other crops, is always a major objective in pepper breeding. Yield in pepper often associates with plant vigor, number, and concentration of fruit set, fruit weight and size, harvesting period. In addition, flowering time, fruit set at extreme temperature, growth habit (adaptation to open field or greenhouse production, mechanical or hand harvesting) are also considered. Besides actual increase in yield, stability of pepper production is equally important.

1.5.2 Breeding for disease resistance

Disease is often the major constraint of pepper production worldwide; therefore, disease resistance is one of the major objectives in pepper breeding and genetic studies (Paran *et al.*, 2004). Pernezny *et al.* (2003) has an overview of most of the known pepper diseases. Resistance sources in wild species or domesticated peppers have been reported for tobacco mosaic virus (TMV) (Boukema, 1980), cucumber mosaic virus (CMV) (Pochard, 1982; Shifriss and Cohen, 1990), potato virus Y (PVY) (Pochard *et al.*, 1983b), pepper ventral mosaic virus (PVMV) (Hobbs *et al.*, 1998), tomato spotted wilt virus (TSWV) (Rosello *et al.*, 1996), bacterial spot (*Xanthomonas campestris* pv. *vesicatoria*) (Hibberd *et al.*, 1983), bacterial wilt (*Ralstonia solanacearum*) (Perera *et al.*, 1992), *Verticillium* wilt (Gil Ortega *et al.*, 1990), *Fusarium* wilt (Jones and Black, 1992), Anthracnose (*Colletotrichum* spp.) (Voorrips *et al.*, 2004), *Phytophthora* root rot, stem rot, and foliar blight caused by *Phytophthora capsici* (Pochard and Daubeze, 1982), and nematodes, etc.

Disease resistance breeding and genetics have been studied extensively in the past years.

Introgression of disease resistance genes from wild germplasm to elite backgrounds contributes significantly in crop improvement, particularly in terms of yield and quality enhancement and stability in pepper production. Successful examples are as follows: resistance to TMV from *C. chinense* (L^3) and *C. chacoense* (L^4) (Boukema, 1980; Berzal-Herranz *et al.*, 1995; De la Cruz *et al.*, 1997), resistance to TSWV from *C. chinense* (Boiteux *et al.*, 1993), and resistance to bacterial leaf spot disease ($Bs2$) from *C. chacoense* (Cook and Guevara, 1984; Kim and Hartmann, 1985; Hibberd *et al.*, 1987) have been introduced to commercial *Capsicum annuum* cultivars. Additional genes for resistance to potyviruses, CMV, nematodes, *P. capsici*, and powdery mildew have been identified in several *Capsicum* species and are being utilized.

However, introgression of disease resistance genes into elite cultivars is particularly difficult when those resistance traits are inherited by complex quantitative mechanism and linked to undesirable horticultural and economic traits, such as low yield and small fruit size. In case of CMV and many other virus diseases, due to recombination and wide diversity of the virus, breeding for sustainable resistance remains a difficult task. With these challenges, breeding for disease resistance remains a prioritized breeding objective in pepper breeding in the future. Identification of new resistance sources, breeding for multiple disease resistances, and pyramiding different sources of resistance will be important in breeding for sustainable agriculture.

1.5.3 Breeding for quality

There are many types of peppers that are being utilized for different purposes, each with different quality requirements and traits required for successful production. A unique aspect of pepper breeding is of course the degree of pungency. Understanding people's diet and favors in terms of pungency level is particularly important in pepper breeding. Pungency level is particularly important for breeding for processed food industry. The industry also emphasizes on color, stability and uniformity of color, and color intensity (Bosland, 1993). For quality control reason, analytical

techniques for both color and pungency are often applied to assist breeding (Pruthi, 2003). For fresh vegetable pepper, major traits under selection are always related to fruit quality and taste: fruit color and color intensity, size, shape, pericarp thickness, taste, and degree of pungency. Furthermore, given the important role of long-distance transportation of vegetable produces now a days, shelf life also becomes an important breeding objective for fresh vegetable pepper. The major market types and their important fruit quality traits were summarized by Poulos (1994). These include fresh consumption; fresh for processing into sauce, paste, canned or pickled product; dried for spice (whole fruits and powder); oleoresin extraction; and ornamental types.

1.6 Tools and Strategies of Pepper Breeding

1.6.1 Classical genetics and conventional breeding

Classical inheritance studies and quantitative genetics have been used to study pepper genetics; conventional breeding methods and strategies have been used for crop improvement in pepper, for instance, single plant selection by pedigree method, population improvement by recurrent selection, backcrossing, single-seed descent (SSD), etc. A set of recombinant inbred lines derived from PSP-11 \times PI201234, produced by SSD has been generated and utilized for breeding and genetic studies of *P. capsici* resistance in pepper (Ogundiwin *et al.*, 2005). For commercial peppers, both open-pollinated and F₁ hybrid varieties are available.

1.6.2 Hybrids

F₁ hybrids (or single-cross hybrids), which are obtained from crossing between two homozygous inbred lines, were firstly used in corn. Now a days, F₁ hybrid cultivars are produced in many other field and vegetable crops. Hybrid cultivars are exploited on the basis of heterosis or hybrid vigor. F₁ hybrid peppers generally show significant improvements in yield, plant vigor, number of fruit set, disease resistance, etc. and have been produced by seed companies worldwide. The drawback of F₁

hybrids is the cost of seed production, as it involves hand emasculation of each flower. The use of male-sterility can, therefore, dramatically reduce the cost of production of F₁ hybrid peppers by eliminating emasculation in hybridization. Cytoplasmic-genic male-sterility, also known as cytoplasmic male-sterility (CMS) was discovered in pepper (*C. annuum* L.) by Peterson in 1958. Pepper CMS system is similar to that found in rice, petunia, and radish. Generally, in CMS system, male-sterility is caused by a cytoplasmic factor (S) and inherited maternally; normal cytoplasm is termed as (N). Recently, an additional abnormal mitochondrial gene *orf456* and a dysfunctioning mitochondrial gene *atp6* have been found in association with male-sterility in pepper (Kim and Kim, 2005, 2006); a dominant nuclear gene, *Rf*, carries out male-fertility restoration. In hybrid seed production, a CMS line (A line), (S) *rfrf*, serves as female and pollinated with a male-fertile restorer line (R line), (N) *RfRf*. A CMS line is maintained by an isogenic male-fertile maintainer line (B line) (N) *rfrf*. CMS system can give rise to 100% male-sterility and has been utilized particularly in hybrid seed production. However, this system tends to be more stable in certain types of hot pepper, for instance, hot dry-type pepper in Korea (Shifriss, 1997; Lee, 2001), but shows instability in other hot/sweet types, especially under low temperatures (Shifriss and Guri, 1979; Shifriss, 1997). R lines are quite common in hot peppers, but rare in sweet peppers (Zhang *et al.*, 2000; Kumar *et al.*, 2001; Yazawa *et al.*, 2002). Pepper types, therefore, restrict the utilization of CMS in hybrid seed production. An alternative male-sterility system, genic male-sterility (GMS), is available and has been used for sweet pepper production. In GMS system, male-sterility is conferred by a pair of homozygous recessive gene (*ms/ms*), homozygous dominant or heterozygous (*Ms/Ms* or *Ms/ms*) plants are male-fertile. To maintain and produce a male-sterile line, two isogenic lines with only difference at the *Ms* locus (*Ms/Ms* and *ms/ms*) are crossed, that gives rise to a progeny mixture of 50% male-fertile (*Ms/ms*) and 50% male-sterile (*ms/ms*) plants. In hybrid seed production field, the male-fertile plants are manually identified and removed, the remaining male-sterile (*ms/ms*) plants are used as female to pollinate with the second parental line (*Ms/Ms*) for hybrid seed production.

1.6.3 Tissue culture in pepper breeding

In vitro haploid plant production is exploited by plant breeders to facilitate the development of inbred lines particularly for hybrid breeding and widely adaptation in various field and vegetable crops. Nitsch and Nitsch produced haploid plants from pollen grains in 1969. A comprehensive protocol for anther culture in pepper was published by Dumas de Valuix *et al.* (1981). Various modifications or improvements of the original protocol have been reported (Qin and Rotino, 1993; Mityko *et al.*, 1995; Mityko and Juhasz, 2006). Other approaches for generating haploid plants have also been studied, including microspore culture and shed-microspore culture (Mityko and Fari, 1994; Supena *et al.*, 2006). In principle of haploid culture, plants are generated directly from haploid gamete ($n = x = 12$ in *C. annuum*), chromosome number of haploid plants is doubled by treating with colchicine and homozygous DH lines are produced (Sopory and Munshi, 1996). Once a protocol is established, robust tissue culture can be carried out to generate a number of DH lines. In conventional breeding, it takes 6–8 generations to produce homozygous inbred lines. In comparison, with haploid and DH technology, number of homozygous DH lines with different recombinant traits can be generated by culturing recombined haploid gametes from hybrid plants. The resulting DH lines are ready for testcross trials for hybrid breeding (Khush and Virmani, 1996). Tremendous time and cost could be saved by this strategy. Furthermore, DH can also be used in other aspects of genetic research, such as in genetic mapping and evaluation of complex quantitative traits (Thabuis *et al.*, 2003, 2004b).

Embryo culture is an important *in vitro* culture technique for plant breeding. One of the most significant applications is to overcome hybridization barrier between distant crosses (Brown and Thorpe, 1995). In the genus of *Capsicum*, only a few species are utilized for cultivation. However, tremendous genetic resources, for instance disease resistance genes, are hidden in other wild species. Most of these species belong to the secondary or tertiary gene pools, where crosses between different species may fail or may give rise to weak or sterile F_1 or backcross plants because of hybridization barriers. Even within the primary gene pool

barriers may occur between *C. annuum*, *C. chinense*, and *C. frutescens*. Hybridization barriers can occur in different stages. Embryo culture is particularly useful to overcome postzygotic or poor endosperm development, where endosperm fails to properly nourish the embryo and seed development is aborted (Brown and Thorpe, 1995). This technique allows researchers and breeders to transfer desirable genes/traits from a wild-related species. In practice, immature embryos are collected after hybridization and transferred to grow on basal growth medium and plants are regenerated from the rescued embryos. In addition, embryo culture can also be utilized in overcoming seed dormancy, slow seed germination, and immaturity in seeds. Besides embryo culture, other methods used to overcome hybridization barrier include using bridge cross through related species, mixing of pollens, and protoplast fusion, etc.

1.6.4 Molecular approaches in breeding

The use of molecular markers and genetic maps in pepper breeding is currently in developmental stage. The aim of molecular breeding is to supplement conventional breeding, to achieve faster and more efficient breeding through marker-assisted selection (MAS) and/or marker-assisted backcrossing (MAB). Molecular markers that are closely linked to the trait of interest are to be identified and applied in gene pyramiding, facilitating introgression of desirable traits into cultivars, early selection, etc. For more complex traits conferred by polygenes, quantitative trait loci (QTL) analysis is carried out. Furthermore, molecular markers and genetic maps also have significant contributions in other plant science research, particularly in map-based cloning.

Molecular markers and genetic maps are important resources for breeding and genetic studies, molecular resources have been building up in the past 20 years. The first generation of molecular markers are protein based isozymes. The first study in which isozymes were used for linkage mapping in *Capsicum* was reported by Tanksley (1984) who mapped 14 isozyme markers in an interspecific cross of *C. annuum* and *C. chinense*, of which nine were arranged in four linkage groups. From the 1990s, different types of DNA markers: AFLP (amplified fragment

length polymorphism), RAPD (random amplified polymorphic DNA), and RFLP (restriction fragment length polymorphism) were applied in pepper. Livingstone *et al.* (1999) used RFLP markers derived from tomato complementary-DNA (cDNA) and genomic DNA of pepper, which also allowed comparative genetic studies between tomato and pepper. Kang *et al.* (2001) developed sets of pepper-specific DNA probes for RFLP system. Toward the 21st century, molecular marker development has preceded to user-friendly polymerase chain reaction (PCR)-based DNA markers. Simple sequence repeat (SSR) markers in pepper are available in both private and public sectors (Lee *et al.*, 2004a; SOL Genomic Networks, <http://www.sgn.cornell.edu>). The future development is expected to move toward development of single-nucleotide polymorphism (SNP) and single-feature polymorphism (SFP) markers. SNP/SFP markers are believed to have the most potential in application of markers in crop improvement.

Several pepper genetic maps have been published in the past, most of these maps were produced in F₂ interspecific crosses: AC99, (*Capsicum annuum* × *C. chinense*) (SOL Genomic Networks); FA03, (*C. frutescens* × *C. chinense*) (Sol Genomic Networks); SNU, (*C. annuum* × *C. chinense*) (Kang *et al.*, 2001); and SNU2, (*C. annuum* × *C. chinense*) (Lee *et al.*, 2004a). SNU2, FA03, and AC99 are SSR-based genetic maps containing 46, 489, and 359 SSR markers, respectively. An integrated map has been developed recently by pooling data of six genetic maps, including two interspecific genetic maps (*C. annuum* × *C. chinense*) and four intraspecific genetic maps (*C. annuum* × *C. annuum*) (Paran *et al.*, 2004). The integrated map covering 1832 cM (centi-Morgans) contains 2262 markers including 1528 AFLP, 440 RFLP, 228 RAPD, 3 isozyme, and 3 morphological markers. This integrated map significantly reduced the length of gaps between markers to 0.8 cM and is expected to serve as an important platform for locating markers and aligning with other pepper genetic maps.

A large number of dominant and recessive genes have been identified and mapped in pepper through both classical and molecular approaches, including other potyviruses (*Pvr4*, *pvr6*) (Caranta *et al.*, 1996; Caranta *et al.*, 1999; Arnedo-Andres *et al.*, 2002) and bacterial spot resistance (*Bs3*) (Pierre *et al.*, 2000); resistance to TSWV (*Tsw*)

(Jahn *et al.*, 2000; Moury *et al.*, 2000), nematodes (*Me3*, *Me4*) (Djian-Caporalino *et al.*, 2001) and TMV (*L*) (Lefebvre *et al.*, 1995). As for more complex disease resistance traits, QTL studies have been carried out for resistance to CMV (Caranta *et al.*, 1997; Ben Chaim *et al.*, 2001; Caranta *et al.*, 2002), potyvirus (Caranta *et al.*, 1996), powdery mildew (Lefebvre *et al.*, 2003), anthracnose (Voorrips *et al.*, 2004) and *Phytophthora* (Nahm, 2001; Thabuis *et al.*, 2003; Thabuis *et al.*, 2004a; Ogundiwin *et al.*, 2005).

To date, two genes have been cloned in pepper conferring disease resistance by candidate gene and map-based cloning approaches respectively: *pvr1* (= *pvr2*), a recessive gene for potyvirus resistance (Ruffel *et al.*, 2002; Kang *et al.*, 2005); *Bs2*, a dominant, disease resistance gene (R gene) for bacterial spot resistance against *Xanthomonas campestris* pv. *vesicatoria* (Tai *et al.*, 1999; Tai and Staskawicz, 2000). Although the progress of gene cloning is relatively slow, with successful gene cloning, PCR-based molecular markers can be developed and applied in plant breeding program (Yeam *et al.*, 2005).

1.7 Limitations of Genetic and Molecular Resources

The current status of genetic and molecular resources limits their use in applied pepper breeding. Genetic resource is extremely important, however, the progress of characterization of collected germplasm is relatively low, for instance, 800 accessions have been characterized for USDA-ARS's *Capsicum* germplasm collection. Furthermore, not many valuable genetic populations, such as nearly isogenic lines, are available in pepper.

As for molecular resources, although the recent publication of the integrated map (Paran *et al.*, 2004) has improved the situation, there is still lack of correspondence between different pepper maps and QTL analyses in pepper (Varshney *et al.*, 2005). Most of these QTL studies relied on AFLP markers, which have relatively low reproducibility and do not include overlapping sets of markers. These studies also suffer to varying degrees from common limitations of QTL analyses: QTL from individual studies may be either overestimated or underestimated because of environmental factors and QTL intervals are

too often very large (Yano and Sasaki, 1997; Carlborg and Haley, 2004). The differences in types of populations, inoculation and scoring methods, and QTL assessment between different studies of *P. capsici* resistance in pepper, may affect estimation of QTL. In addition, resolution of QTL was further constrained by limited polymorphism often due to lack of polymorphism in intraspecific populations. Considering the limitations of QTL analysis and genomic resources in pepper, the diversity of the pathogens, and the complexity of genetic resources for resistance, molecular markers have important potential for MAS in pepper. Particularly, breeding for complex disease resistance traits in pepper remains a challenge for plant breeders.

With the limitations of genetic and molecular resources, genetic transformation provides an alternative approach for crop improvement in *Capsicum*. Transformation further overcomes the barriers between different species and allows us to introduce “useful” genes or novel traits into pepper.

2. DEVELOPMENT OF TRANSGENIC PEPPERS

2.1 Donor Genes: Sources, Isolation, Cloning and Designing Transgenes

The first pepper transformation was reported in 1990 (Liu *et al.*, 1990). However, Liu and his colleagues failed to regenerate the transgenic pepper plants. In fact, whole plant regeneration of pepper has been known as difficult with poor reproducibility that has been a key limiting factor for pepper transformation. Several studies on establishing and optimizing protocols for reliable regeneration have been reported in the past 15 years (Lee *et al.*, 1993; Manoharan *et al.*, 1998; Mihalka *et al.*, 2000; Kim *et al.*, 2002; Li *et al.*, 2003). Recently, Lee *et al.* (2004b) have reported an improved protocol by callus-mediated shoot formation. Despite these efforts, pepper transformation and regeneration efficiency are relatively poor comparing with that of other solanaceous crops, such as tomato and tobacco, where transformation protocols are well developed and have been routinely used for both biological studies and crop improvement.

Summaries of pepper transformation, regeneration methods and medium used for pepper transformation are presented in Tables 1 and 2, respectively. Besides establishing transformation and regeneration protocol, researchers are mostly interested in pepper transformation for disease resistance, particularly, virus resistance (Table 1). It has been found that by introducing viral gene(s) to the host plant, transgenic plants displayed resistance to the target and related virus. This disease resistance mechanism was first demonstrated by Abel *et al.* (1986) by transforming coat protein (CP) encoding gene of TMV into tobacco; the transgenic plants showed delay of disease development when infected with TMV and related tobamoviruses (Abel *et al.*, 1986; Beachy, 1999). Based on this resistance mechanism, pepper transformation has been studied by different research groups for resistance to TMV by introducing *TMV-CP* gene (Lee *et al.*, 2004b), pepper mild mottle virus (PMMV) by Pepper-PMMV interaction 1 transcription gene (Lee *et al.*, 2004b), tomato mosaic virus (ToMV) by *ToMV-CP* gene (Shin *et al.*, 2002b), CMV by *CMV-CP* gene (Shin *et al.*, 2002a) and CMV-satellite RNA (Kim *et al.*, 1997). Such transgenic virus resistance mechanism was later known as RNA silencing (Voinnet, 2001). Production of transgenic peppers by RNA silencing approach is considered to be specific and effective against targeted virus and/or viral groups.

Other donor genes might be used for developing broad-spectrum resistance in pepper (Table 1). Shin *et al.* (2002b) demonstrated transformation into and overexpression in pepper of *Tsi1*, a tobacco pathogenesis-related (PR) gene and the resulting transgenic plants displayed resistance or improved resistance to a broad spectrum of pathogen types including PMMV, CMV, a bacterial pathogen *Xanthomonas campestris* pv. *vesicatoria* and an oomycete pathogen *P. capsici*.

Besides transformation for disease resistance, studies on other aspects of transformation in pepper are limited. In other plants like *Arabidopsis*, tobacco, and tomato, transformation technology is also widely applied for functional studies of genes. Due to preliminary transformation technology in pepper, study on gene expression in transgenic pepper is extremely rare. Characterization of isolated pepper genes has not been carried out by transformation in foreign plants. With

Direct regeneration	MS salts, B5 vitamins, 2% sucrose, kanamycin (500 mg l ⁻¹), IAA (1.0 mg l ⁻¹), BA (3.0 mg l ⁻¹), AgNO ₃ (5.0 mg l ⁻¹), AgNO ₃ (10 mg l ⁻¹), DJ nutrients (5000 mg l ⁻¹ ; prepared in this study)	MS salts, B5 vitamins, 2% sucrose, kanamycin (500 mg l ⁻¹), IAA (1.0 mg l ⁻¹), BA (3.0 mg l ⁻¹), AgNO ₃ (10 mg l ⁻¹), DJ nutrients (5000 mg l ⁻¹ ; prepared in this study)	MS salts, B5 vitamins, 2% sucrose, NAA (0.2 mg l ⁻¹), IAA (0.1 mg l ⁻¹)	81.3% (differentiation); 61.5% (elongation); 89.5% (rooting)	40.8% of regenerated plants	Li <i>et al.</i> , 2003
Direct regeneration	MSB5gl medium, cefotaxime (500 mg l ⁻¹)	MSB5gl medium, cefotaxime (300 mg l ⁻¹)	MS basal medium, glucose (15 mg l ⁻¹), maltose (15 mg l ⁻¹), IAA (0.5 mg l ⁻¹); MS basal medium, glucose (15 mg l ⁻¹), maltose (15 mg l ⁻¹), kanamycin (150 mg l ⁻¹)	–	2.4%	Mihalka <i>et al.</i> , 2003
Indirect callus-mediated shoot regeneration	MS medium, kanamycin (80–100 mg l ⁻¹), cefotaxime (300 mg l ⁻¹) or lincillin, zeatin (2.0 mg l ⁻¹) + NAA (0.5 mg l ⁻¹) or zeatin (2.0 mg l ⁻¹) + IAA (0.1 mg l ⁻¹)	MS medium, kanamycin (60–100 mg l ⁻¹), cefotaxime (300 mg l ⁻¹), zeatin (2.0 mg l ⁻¹) + NAA (0.01 mg l ⁻¹) or zeatin (2.0 mg l ⁻¹) + IAA (0.01 mg l ⁻¹)	MS medium, kanamycin (20–30 mg l ⁻¹), cefotaxime (200 mg l ⁻¹)	28/37 500 (number of shoots with roots/ number of explants)	0–0.19%	Lee <i>et al.</i> , 2004b

an exception, Harpster *et al.* (2002), who demonstrated suppression of a ripening-related endo-1,4- β -glucanase in transgenic pepper. On the other hand, transformation of foreign genes identified in other plant species into pepper is also uncommon. Nonetheless, by transformation and constitutive expression of a rice gene, *OsMADS1*, a dwarf transgenic pepper was successfully produced (Kim *et al.*, 2001).

Classical transgene designs have been used in pepper transformation (Table 1). The transgene construct, which contains β -glucuronidase (GUS) gene as reporter gene, driven by cauliflower mosaic virus (CaMV) 35S promoter and with nopaline synthase (NOS) as terminator, is dominated in pepper transformation studies, particularly for the studies aiming at establishing and optimizing pepper transformation protocol (Liu *et al.*, 1990; Manoharan *et al.*, 1998; Li *et al.*, 2003; Mihalka *et al.*, 2003). CaMV 35S promoter is commonly used for overexpression of genes of interest (Zhu *et al.*, 1996; Kim *et al.*, 2002; Shin *et al.*, 2002b; Lee *et al.*, 2004b).

2.2 Methods Employed

2.2.1 *Agrobacterium*-mediated transformation

Agrobacterium-mediated transformation system is commonly employed for pepper transformation. Other transformation systems, for instance gene gun, have not been reported. Wild type *A. tumefaciens* generally is not considered as a pathogen of *Capsicum* spp. under field conditions, although certain strains of *Agrobacterium* showed virulence to pepper (De Cleene and De Lay, 1976). Capability of *Agrobacterium* strains to induce gall formation under laboratory conditions is required for successful genetic transformation. Use of strains also determines the efficacy of transformation (Liu *et al.*, 1990; Mihalka *et al.*, 2000). Liu *et al.* (1990) compared the effect of two different *Agrobacterium* strains in pepper transformation. The strain C58 consistently showed distinctively higher average percentage of explants forming tumors than the strain A281.

Cotyledons and/or hypocotyls are the most commonly used explants (Manoharan *et al.*, 1998; Pozueta-Romero *et al.*, 2001; Kim *et al.*, 2002;

Lee *et al.*, 2004b). In addition, use of young leaf for pepper transformation has also been demonstrated (Liu *et al.*, 1990; Zhu *et al.*, 1996). For transformation, *Agrobacterium* is co-cultured with the pepper explants in Murashige and Skoog (MS) medium (Pozueta-Romero *et al.*, 2001; Lee *et al.*, 2004b) or MSB5gl medium (MS salts with B5 vitamins and glucose) (Mihalka *et al.*, 2000, 2003).

Different pepper cultivars/genotypes also show variation in response to *Agrobacterium*-mediated transformation (Liu *et al.*, 1990; Lee *et al.*, 2004b). Transformation has been carried out mainly in *C. annuum*, both chili pepper and sweet pepper (Zhu *et al.*, 1996; Manoharan *et al.*, 1998); transformation of other *Capsicum* spp. is rarely tested except for *C. frutescens*.

2.2.2 Selection of transformed tissue

Antibiotic resistance has been the most commonly used method for the selection of transformed pepper tissue (Table 1). To screen for positive transformation, explants are transferred to antibiotic-containing medium after transformation or gall formation for selection, positive transformants with antibiotic resistance would survive. Similar to other protocols for selection of transformants in other plants, kanamycin resistance is commonly used for selection in pepper transformation. Kanamycin resistance is contributed by the neomycin phosphotransferase II gene (*nptII*) in the vector construct (Liu *et al.*, 1990; Kim *et al.*, 1997; Manoharan *et al.*, 1998; Mihalka *et al.*, 2000; Pozueta-Romero *et al.*, 2001; Shin *et al.*, 2002a, b; Li *et al.*, 2003). *NptII* is usually driven by a NOS gene promoter (Manoharan *et al.*, 1998; Kim *et al.*, 2002; Li *et al.*, 2003). *NptII* confers resistance to kanamycin as well as geneticin. Alternative selection markers for pepper transformation have been demonstrated to be effective by using hygromycin resistance gene (*hpt*) for hygromycin resistance, methorexate resistance gene (*dhfr*) for methorexate resistance and phosphinothricin acetyltransferase gene (*bar*) for phosphinothricin resistance (Mihalka *et al.*, 2000).

However, use of antibiotic or herbicide resistance genes as selection markers for transformation has risen environmental and health concerns.

Alternative selection methods have been investigated. Shin *et al.* (2002a) discussed the potential use of ToMV-CP gene as a selection marker. In this screening system, TMV is inoculated to the transgenic plants and positive transformants are identified by a distinctive hypersensitive response. However, further experiment is necessary to evaluate the efficiency and effectiveness of this selection system.

Another alternative selection system was demonstrated by transformation and expression of isopentenyl transferase gene (*ipt*) identified from “shooter” mutants of *Agrobacterium* (Mihalka *et al.*, 2003). With the presences of *ipt*, positive transformants were shown to produce direct shooting on growth regulator-free medium. The significant morphological characteristic allows visual selection of positive transgenic plants. This system has also been demonstrated in transformation of other crops like tomato, tobacco, and muskmelon. The use of binary vector in pepper transformation has also been reported (Mihalka *et al.*, 2003). Selection markers, which might carry undesirable genes, and the genes of interest are integrated in different chromosomal positions in the transgenic pepper under the binary vector system. Therefore, selection marker genes could easily be removed subsequently.

2.2.3 Regeneration of whole plants

Regeneration of pepper plants has long been a challenging task for pepper transformation studies. Several studies attempted to improve, modify, and optimize protocols for regeneration of transgenic pepper plants. However, these experiments are often hardly reproducible.

Direct regeneration from shoot is the most common practice for transgenic pepper regeneration. In this system, explants transformed with *Agrobacterium* are grown on shoot inducing medium or selection medium for 3–4 weeks, shoots or multishoots are formed directly at the sites of wounded explants. Then induced shoot buds are transferred to the elongation medium and grown for 20 days to 8 weeks. The shoots formed are excised and grown on root-inducing medium. Recently, an alternative regeneration method, named callus-mediated shoot formation, has been proposed (Lee *et al.*, 2004b). In this study,

six different types of callus have been identified from transformed tissue and two of which were able to form shoots. Desirable type of callus were isolated and propagated (instead of direct shooting); propagated transformed callus was then subcultured for shoot formation. Although the transformation rate remains low (<0.19%), callus-mediated shoot formation method is believed to be more reproducible and reliable. More detailed protocol of this approach is presented in the next section.

MS medium is used as basal medium for transgenic plant regeneration, depending on the research group; different concentrations and compositions of supplements were applied (Table 2). Particularly, effects of hormones have been studied by several research groups with the aim of optimizing regeneration conditions. Nevertheless, there was lack of consensus between different research groups. Different compositions and ratios of cytokinins (benzyladenine, BAP), thidiazuron (TDZ), naphthalene acetic acid (NAA), zeatin, (2-isopentyl adenine (2IP)) to auxin (indol-3-acetic acid, IAA) have been tested (Lee *et al.*, 1993; Zhu *et al.*, 1996; Manoharan *et al.* 1998; Mihalka *et al.*, 2000; Li *et al.*, 2003). Furthermore, kanamycin in media is commonly used for selection of positive transformants. Concentration and effects of other antibiotics (geneticin, hygromycin, methorexate, phosphinothricin) in the regeneration media have also been studied (Mihalka *et al.*, 2000). In addition, effects of other important factors on regeneration have been studied, for instance, effect on explant tissue for shoot bud initiation (Zhu *et al.*, 1996), genotypes/cultivars used for plant transformation and regeneration (Liu *et al.*, 1990; Kim *et al.*, 2002; Lee *et al.*, 2004b).

2.3 Case Study: Transformation Using Callus-Mediated Indirect Regeneration Method

Most of the previously described transformation procedures for pepper transformation are not very useful for routine transformation due to the lack of reproducibility. The low rate of pepper transformation indicates that DNA transfer via *Agrobacterium* infection into cut-injured cotyledon or hypocotyl tissues hardly occurs. This also suggests that *Agrobacterium* may not

penetrate and/or infect cotyledon or hypocotyl tissues of pepper. Lee *et al.* (2004b) demonstrated that selection of the right callus type is most critical for successful pepper transformation. Indeed, the transformation via callus-mediated shoot formation proved to be reproducible and this selection method provided a reliable system for pepper transformation. The protocol for successful pepper transformation and the results obtained using the protocol are described below.

2.3.1 Transformation protocol

Seeds from commercial inbred lines (*C. annuum* inbred line P915, P409, P410, P101: Nongwoo Bio Co. proprietary) are commonly used for the experiment. These lines showed a very high rate of regeneration (90%) among the 30 inbred lines tested (Kim *et al.*, 2002).

2.3.1.1 Germination and explant

Seeds are surface-disinfested in 95% ethanol for 30 s, 50% bleach for 10 min and rinsed three times with sterilized water. Sterilized seeds are then placed in 1/2 MS medium (Murashige and Skoog, 1962) and allowed to germinate in light or dark at 25°C. Germination under light or dark conditions does not influence the transformation rate. Cotyledons and hypocotyls from 8- to 10-day-old plants are excised and used as explants.

2.3.1.2 Preculture and *Agrobacterium* inoculation

Explants are transferred to a pre-culture medium consisting of MS medium supplemented with zeatin 2 mg l⁻¹ and NAA 0.05 mg l⁻¹ or IAA 0.1 mg l⁻¹, and placed in light room at 25°C for 2–36 h and this preculture step is necessary. For transformation, *Agrobacterium* strain EHA105 is the best choice for the pepper transformation. *Agrobacterium* is grown in YEP (2% bacto peptone; 1% yeast extract) media supplemented with kanamycin 50 mg l⁻¹, rifampicin 50 mg l⁻¹ and 100 µM acetosyringone. The *Agrobacterium* culture is centrifuged and then diluted with MS to optical density 0.3–0.8. This bacterial suspension

is then mixed with MS liquid containing 100 µM acetosyringone and inoculated to explants for 10–20 min, co-cultured in dark for 38–96 h and then washed with cefotaxime 500–800 mg l⁻¹ or lilacilline 500–800 mg l⁻¹ three times.

2.3.1.3 Callus and shoot formation

In order to obtain callus formation and development, explants are transferred to a selection medium consisting of 80–100 mg l⁻¹ kanamycin, 300 mg l⁻¹ cefotaxime or lilacilline with zeatin 2.0 mg l⁻¹ + NAA 0.05 mg l⁻¹ or IAA 0.1 mg l⁻¹ for 6–8 weeks. For shoot formation and elongation, the calli are transferred to a regeneration medium consisting of 60–100 mg l⁻¹ kanamycin, 300 mg l⁻¹ cefotaxime with zeatin 2.0 mg l⁻¹ + NAA 0.01 mg l⁻¹ or IAA 0.01 mg l⁻¹ for 7–10 weeks.

2.3.2 Transformation experiment using the protocol

Two general patterns of pepper shoot formation were identified. Firstly, a shoot or multishoots formed directly from the wounding or cut region of explants (direct regeneration) (Figure 1). This pattern was frequently observed in many cases of pepper transformation and the stages of shoot development observed were direct shoot formation, multishoot elongation, shoot elongation, and root formation. Secondly, shoots were selected from callus tissues that had formed around cut after 4–5 weeks after culture on the shoot selection medium (callus-mediated indirect regeneration) (Figure 2) These were unusual because calli are not easily formed from the wounded region of cotyledons. Five stages of shoot development were distinct: callus formation, callus development, shoot formation, shoot elongation, and root formation. Six different types of callus developed from the explants have been identified. Shoot regeneration capability was dependent on the callus types. Those that were able to form shoots were designated type A (white hard surface and green tissue inside) and type B (dark green callus with hard surface, but a little bit moist) (Figure 3). The regeneration rate of type A was much higher than that of type B (ca. 90%, data

Figure 1 Development of direct shoot formation after co-culture: (a) shoot formation (5 weeks old on selection medium); (b) multishoot formation (7 weeks old); (c) multishoot elongation (9 weeks old); (d) a single shoot elongation from multishoot; (e) root formation (14 weeks old) (the red dot line indicates a cut to move to the next culture)

Figure 2 Development of indirect shoot formation after co-culture: (a) callus formation (5 weeks old on selection medium); (b) callus development (7 weeks old); (c) shoot formation (9 weeks old); (d) shoot elongation (11 weeks old); (e) root formation (14 weeks old) (the red dot line indicates a cut to move to the next culture)

Figure 3 Callus types for shoot formation (a and b) and for nonshoot formation (c, d, e, f): (a) white hard surface and green tissue inside; (b) dark green callus with hard surface, but a little bit moist; (c) yellow and easily brittle; (d) yellow and hard surface; (e) moist and a little bit transparent; (f) green, moist, and easily brittle

not shown). The callus types that were not able to produce shoots were designated type C (yellow and brittle) and also included type D (yellow and hard surface), type E (moist and a little transparent), and type F (green, moist, and brittle).

In order to investigate the direct shoot formation rate after transformation, 151 700 explants from four different lines were transformed with the *TMV-CP* and *PPII* genes. The rate of developing a direct shoot in the shoot medium after co-culture was 5.3% (8089/151 700) (Table 3). The rate of shoot survival in the rooting medium was 0.93% (1407/151 700). Among four lines, P915 line

showed the highest rate of shoot development. There was no significant shoot formation rate between transformation experiments of two genes. To find the indirect shoot formation rate, 37 500 explants from four different lines were transformed with the *TMV-CP* and *PPII* genes. The frequency of generating calli from explants was 1.2% (459/37 500) (Table 4). However, all calli did not produce the shoot. The frequency of shoot development from callus was 11.6% (53/459). The frequency of root formation from the callus-mediated shoots was 52.8% (28/53). Out of four lines, 68% (19/28) of the total shoots

Table 3 Frequency of direct shoot formation

in the rooting medium were obtained from P915 line, suggesting a genotype preference of shoot formation.

A total of 1407 direct shoots grown in the rooting media were tested by PCR to identify transformed pepper plants and none of the shoots contained inserts (Tables 3 and 5). This indicates that the direct shoots grown from explants are not transformed. To test the transformation rate of indirect callus-mediated shoots, the final 28 shoots in the rooting medium were analyzed by PCR (Tables 4 and 5; Figure 4). The transformation rate was 0.19% (15/37, 500) for P915 line and 0.03% (3/37, 500) for P409 line. However, the transformation rate as determined by the number of PCR positive versus the number of callus-mediated shoot was 34% (18/53), indicating that shoots grown from the callus could be transformed with high probability. Therefore, the selection of a callus-mediated shoots from among a large number of shoots growing on selection medium tended to discriminate transformed plants from nontransformed plants.

DNA samples from transformed peppers (T_0), randomly chosen from the PCR positive peppers, were isolated and 30 μ g DNA was digested to completion with *Xba*I for *TMV-CP* and *Bgl*II for the *PP11* gene. Figure 5a shows a Southern

blot analysis of *TMV-CP* transformed peppers digested by *Xba*I. Transformed peppers showed different *TMV-CP* insertion sites and those had one copy of *CP* gene inserted. The *PP11* insert digested with *Bgl*II was also localized at different sites in *PP11* transformed peppers (Figure 5b). The 5-kb band on the Southern blot was present in all T_0 plants, and represented the pepper *PP11* gene internally embedded in the genome, whereas the other inserts were newly transformed. Interestingly, all of the transformed peppers had only one copy of the *PP11* gene inserted.

In summary, the protocol described here provides a more reliable pepper transformation platform. However, several key points should be taken into account for successful transformation. First, plant material for pepper transformation is critical. For maximum transformation efficiency, callus-mediated indirect shoot should be used. Most shoots seem to grow well directly from the wounded surface of explants on selection medium, however, no transformants have been obtained from shoots grown directly. In contrast, callus-mediated indirect shoots showed very high-transformation efficiency. Another important factor is to select a right callus type, which can produce transgenic shoot. Among the six different callus types, the type A callus generated most

Table 5 Transformation efficiency of direct and indirect shoot formation

Gene	Direct shoot				Indirect shoot

Transformation rate ^(a) (%)	0	0	0	0	0.19	0.03	0	0%

^(a) Percentages were obtained by dividing the number of PCR positive with the number of explant used

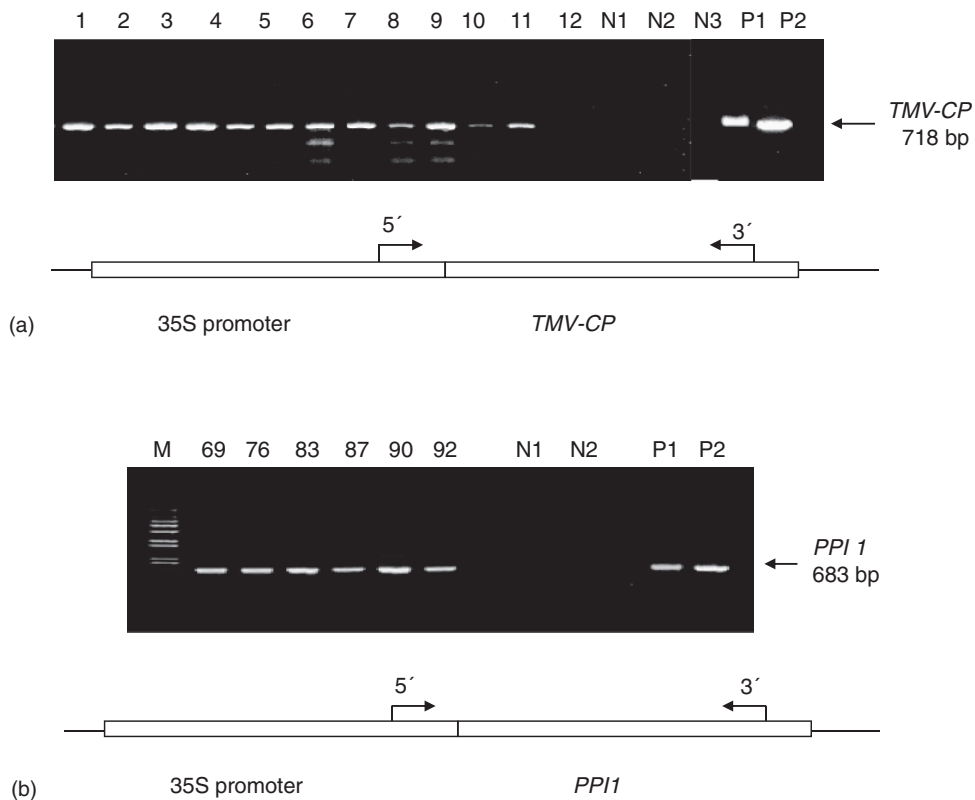

Figure 4 (a) PCR analysis of transformed peppers with *TMV-CP* gene (T_0): 1–12, transformed; N1–N3, nontransformed; P1–P2, positive control (cloned bacterial cell and p*TMV-CP*, respectively) (b) PCR analysis of transformed peppers with *PPI1* gene (T_0): 69, 76, 83, 87, 90, and 92, transformed; N1–N2, nontransformed; P1–P2, positive control (cloned bacterial cell and p*PPI1*, respectively)

Figure 5 (a) Southern blot analysis of transformed peppers with *TMV-CP* gene (T_0): 5 and 63, transformed; N1–N2, nontransformed (b) Southern blot analysis of transformed peppers with *PPI1* gene (T_0): 69, 76, 83, and 87, transformed; N1–N2, nontransformed (the 5.0-kb band belongs to the endogenous gene of *PPI1*)

transgenic shoots. Therefore, the best way to screen putative transformed shoots during the pepper transformation procedure is to identify shoots regenerated from type A callus. Thirdly, plant genotypes and *Agrobacterium* strains for the transformation are very important factors. Therefore, regeneration rate of each pepper line should be tested. The higher regeneration rate produces the better transformation rate. According to our experimental results *Agrobacterium* strain, EHA105, is best strain for pepper transformation.

3. FUTURE ROAD MAP

Capsicum transformation is still at its infant stage comparing with that of other well-studied solanaceous crops, such as tomato and tobacco. Therefore, no transgenic pepper lines are under field test; no GM pepper varieties have been commercialized. In spite of continuous efforts worldwide, successful reports of pepper transformation are very rare. Even among the successful groups, the transformation efficiencies have been extremely low and inconsistent. We presented a callus-mediated indirect shoot transformation method and expect that this will provide a better platform for pepper transformation.

Nevertheless, further improvement in transformation efficiency is required. Since both transformation efficiency and plant regeneration is genotype dependant. In order to obtain maximum transformation rate and for routine transformation, the most virulent/effective *Agrobacterium* strain and the most susceptible pepper genotypes with the highest regeneration rate should be identified. Genotypes with the highest transformation rate do not necessarily regenerate well (Liu *et al.*, 1990). However, screening large numbers of pepper inbred lines may require joint efforts of laboratories worldwide.

Since pepper transformation efficiency is extremely low at present, introducing transgenes to elite lines can also be very slow even if any useful transgenic lines may be available. In order to expedite transgene introgression, conventional backcrossing and molecular marker technique should be utilized. Molecular linkage maps and various types of molecular markers are currently available for genome scanning and marker-assisted selection. Hence, as was shown in soybean and

other well-studied field crops, useful transgenes are transferred to the genotype, which can be easily transformed, and introgressed by backcrossing to elite lines those are recalcitrant to be transformed.

Virus resistant peppers are expected to be the first possible commercialized transgenic peppers because these traits have been most extensively studied and are relatively simple to manipulate. For virus resistance, virus CPs are easiest target genes to be transformed into pepper. For instance, CMV resistant transgenic peppers harboring CMV-CP gene are very promising future product. In addition to viral genes, engineering host factor can be a target for virus resistance. Since disease resistance breeding by conventional method relies on the availability of disease resistance gene(s) in existing *Capsicum* germplasm and confined by sexual barriers between domesticated and wild *Capsicum* species. Transformation technique is, therefore, extremely useful against potential pathogens when there is lack of genetic resources among available *Capsicum* species.

Although insect resistance has not been a dominated research target in the past pepper transformation studies, *Bacillus thuringiensis* (*Bt*)-transgenic pepper also has potential to be commercialized (if it is available), particularly when political and regulatory issues are considered. Transformation of *Bt*-gene, mainly *Cry1Ac*, for insect resistance has been demonstrated in many other crops and the related products have been tested extensively and released for commercial production for long time; health and environmental assessments and regulations; administrative and political processes for the release of *Bt*-transformed products are well established. In fact, release of *Bt*-transgenic eggplant (another closely related relative) in several targeted Asian countries is under progress. These experiences in *Bt*-transformed products and *Bt*-GM eggplant will serve as an example for future release of *Bt*-pepper.

Since for breeding pungency level is particularly important and difficult object, development of transgenic plant with different pungency level will be very useful approach. The gene, which controls presence and absence of capsaicinoid, was recently identified as acyltransferase 3 (*AT3*) and expression level of this gene controls pungency level. Therefore, it is theoretically feasible to control pungency level by controlling expression level of *AT3*. Other possibility of transgenic pepper

development is biofortification for micronutrient enhancement. Although peppers are rich in vitamin A and C, transformation approach for further increase or stable vitamins' production will benefit consumers and growers/manufacturers as well particularly in the areas with malnutrition problems.

Finally, once transgenic pepper plants are developed, potential risks should be addressed. For example, damage to human health and environment, disruption of current cropping schemes and food production in developed countries, and of traditional practices and economies in less developed countries, the regulatory measures adopted by Institutional Biosafety Committee (IBC), Animal and Plant Health Inspection Service (APHIS), Food and Drug Administration (FDA), Environmental Protection Agency (EPA), and international agreements for new transgenic products are also to be considered.
